INDEX TO VOLUME I FOR 1945

READERS in search of a particular subject will find it useful to bear in mind that the references are in several cases distributed under two or more separate headings—for example, Brain and Cerebral; Heart and Cardiac; Liver and Hepatic; Renal and Kidney; Cancer and Carcinoma; Child and Infant; Goitre and Thyroid. Subjects dealt with under various main headings in the JOURNAL have been set out in alphabetical order under their respective headings—for example, "Annotations," "Correspondence," "Leading Articles," "Obituary," "Reviews," etc. Original Articles are indicated by the letter (O).

A

ABBOTT, W. N.: Aetiology of erythema nodosum, 386
Abdomen: Underwater blast injuries of, 24—Headache and "acute abdomen," 70, 140—Spinal analgesia in penetrating wounds, 129—Surgery and anaesthesia of war wounds of abdomen (S. O. Aylett and A. F. Alsop), 547 (O); correspondence, 713, 715—A case of gunshot wound of abdomen (R. K. A. van Someren and J. D. [illegible]ycock), 595—Diagnosis of doubtfully penetrating abdominal wounds: a lesser operative procedure (Charles Donald), 502 (O)
[illegible]: *See* Obstetrics
[illegible] Sir Adolphe: Physical training of patients, 195—Therapeutic illness?, 383—Rheumatism: postgraduate instruction, 671 (O); correspondence, 854
[illegible] A. M.: Cutaneous anthrax treated with penicillin, 771
Académie des Sciences: Elections, 103
Academy, New York, of Medicine: Gold medal presented, 102
—— Royal, of Medicine in Ireland:
Section of Obstetrics: Treatment of breech presentation, 306—Exfoliation of bladder lining, 420
Acariasis, pulmonary: a possible cause of asthma (E. Soysa and M. D. S. Jayawardena), 1 (O); leading article, 18
[illegible], incidence of, in a group of 500 women (E. L. Cohen), 493
Acroparaesthesia, 397
ADAMS, A. Wilfrid: Nursing in the new health services, 716—An examination paper for nurses, 957
—— John C. L.: Final M.B. of London University, [illegible]
Adder-bite, a case of (E. R. Williams and A. B. Davies), 223
[illegible], W. R.: Primary carcinoma of Fallopian tube, 619
Adiposis dolorosa, 354
Adolescents, physical training of (R.S.M.), 195
Adrenalectomy: A further case of paranoid psychosis successfully treated by adrenalectomy (Clifford Allen and L. R. Broster), 696 (O); correspondence, 787, 823—Hypertrichosis with mental change: effect of adrenalectomy (Raymond Greene and others), 698 (O)
Adrenaline: Injections, 67—In treatment of malaria, 567—As an analgesic (annotation), 636—And the heart, 862
Adrenals: Problems of cortical hyperadrenalism, 533—Adreno-genital syndromes, 420—Necrosis of liver and bilateral massive suprarenal haemorrhage in the puerperium (Gladys H. Dodds), 769 (O)
Aerosols in theory and practice (book review), 912
[illegible]: The sick African (book review), 414
[illegible] T. (and others): Clinical features of the poliomyelitis epidemic in Malta, 1942–3, 759; leading article, 773
[illegible]ELDT, R. H.: Neurone, mind, and crime, [illegible]
[illegible]TH, R. M. (and H. Bathurst NORMAN): Staphylococcal pyopericardium (complicating [illegible] fever) treated with penicillin, 806 (O)
[illegible]TH-DAVIS, J. C.: Sulphonamides in urinary disease, 674
[illegible]: Aerial infection (Maurice Mitman), 71 (O); correspondence, 383—Coal and atmospheric pollution (A. Parker), 419—Chemical disinfection (leading article), 914
—— expired, humidity and temperature of, 828
[illegible]TER, Edward: *Practical Wound Treatment*, 299
Albuminuria, emotional (annotation), 269
[illegible] Arnold: Sulphonamide-resistant penicillin-[illegible] 735
[illegible]en Bower: Shall we nationalize medicine? [illegible]
Alcohol: "Under the influence," 317
[illegible]NDER, A. B.: ? Otitic barotrauma, 276—Once again barotrauma, 570
—— James Whitelaw, obituary notice of, 682
—— R. S. (and R. P. WARIN): Splenomegaly in bacillary dysentery, 187
Alimentary obstruction, oranges causing (Alwyn S. [illegible]es and S. W. Vivian Davies), 735
Alkaloids in plants, function of, 863
—— Alexander Smith, obituary notice of, 498
ALLEN, Clifford (and L. R. BROSTER): A further case of paranoid psychosis successfully treated by adrenalectomy, 696 (O); correspondence, 787, 823
—— F. M. B. (and W. H. RUTHERFORD): Gastric drip infusion to combat dehydration in infants, 46
—— F. R. W. Kinkead: Retention of urine, 309—Ovariotomy or Caesarean section? 784
—— Major George Leverstone, obituary notice of, 717
—— and Hanburys Ltd.: Antiscorpion serum, 830
—— H. Sandeman (and Victor BONNEY): Skin sterilization by colourless flavine, 25
Allergy: Mixed inhalant solutions for, 33—To milk, 67—Vaccination of an allergic subject, 105—To citrus fruits, 106—Mould allergy (E. M. Fraenkel), 379—To liver extracts, 617—Soya bean, 750
ALLPORT, Noel L.: *Colorimetric Analysis*, 518
ALSOP, A. F. (and S. O. AYLETT): Surgery and anaesthesia of war wounds of abdomen, 547 (O); correspondence, 713, 715
AMBERSON, J. Burns (and others): *The* 1944 *Year Book of General Medicine*, 224
AMBROSE, Arthur J.: Impetigo, 276
Amputations: The stump in health and disease, 56—The extremities, and prosthesis, in U.S.S.R. (Nikolai N. Priorov), 178 (O)—Osteoplastic re-amputation of thigh (Alexander Kotov), 179 (O); leading article, 189

ANAEMIA:
  Haemin and anaemia, 244
  Haemolytic, recurrent: case in a male infant (J. K. David and A. S. Minot), 662
  Hypoproteinaemia during recovery from severe anaemia (Trevor Davies), 45 (O); correspondence, 129, 164
  Iron-deficiency, in N.W. Indian soldiers (Martin Hynes and others), 626 (O)
  Nutritional macrocytic, and the animal protein of diet (Geoffrey F. Taylor and P. N. Chhuttani), 800 (O)
  Sickle-cell, a case of, simulating coronary occlusion (S. L. Zimmerman and R. Barnett), 520

ANAESTHESIA:
  Abdomen, surgery and anaesthesia of war wounds of (S. O. Aylett and A. F. Alsop), 547 (O); correspondence, 713, 715
  Anaesthetic mask, civilian respirator as, 131, 199, 234, 309
  Art of (book notes), 702
  Caesarean section, anaesthesia for, 886
  Clausen's harness: a disclaimer (R. J. Clausen), 97
  Diabetes: Preparation of diabetic patients for operation (R.S.M.), 710
  Endotracheal connector, safety (A. Owen-Flood), 371
  Facepiece, anaesthetic, for use in thoracic surgery (H. J. V. Morton), 16
  Gas cylinders, identification of, 381, 457, 535, 686
  Hypotony, unilateral, during (Ina Brittain and G. J. C. Brittain), 442 (O); correspondence, 566
  Intravenous: For torn perineum, 104, 318—With pentothal sodium (Barnet Solomons), 592 (O)
  Mortality, 503
  Obstetrics: Anaesthetic for a primigravida with tuberculosis, 33—Chloroform in midwifery, 172—Intravenous pentothal in placenta praevia, 642, 713
  Quinsy: Anaesthetic for excision, 469
  Shock, anaesthesia in, 162
  Technique, improvement in: "It can be done," 715
  Textbook of anaesthetics (book review), 15

ANALGESIA:
  Adrenaline as an analgesic (annotation), 636
  Caudal: Dangers of, 746, 925—A rational assessment, 821
  Etherington-Wilson method, 198
  Midwifery, 720
  Novocain injections, 208
  Spinal, in penetrating abdominal wounds, 129, 198
  Trichlorethylene in midwifery, 422, 566

Anatomist of Melancholy (book review), 736
Anatomy: Companion to manuals (book review), 335—Motor nerve supply to tongue and lips, 792
ANDERSON, A. B.: A nomogram for percentage increase of body weight over ideal weight, 120
—— Charles Macdonell, obituary notice of, 350
—— I. G.: Antibiotic action of moulds, 504
—— Robert: Artificial insemination, 165—Intestinal obstruction by gall-stone, 794
ANDROSS, Mary: Losses of nutrients in preparation of foodstuffs, 917
Anencephaly, 105
Aneurysm, intracranial, review of book on, 154; leading article, 150
Angina and coronary occlusion, 172
—— Ludwig's (John Farr and E. D. Stanhope), 295 (O); correspondence, 384, 457
Angioma, cavernous, 354
Anglo-American Consultants Conference, 85

Annotations:
  "A House of Books" (H. K. Lewis & Co., Ltd.), 52
  Adrenaline as an analgesic, 636
  Albuminuria, emotional, 269
  Antibiotics from plants, 776
  Antiseptics, intestinal, 157
  Arterial injuries, 376
  Assistants and locums under "pay-as-you-earn," 126
  Association, British Medical, Presidency of, 669
  —— of Surgeons, 669
  Barotrauma, 490
  Birmingham United Hospital, 847
  Blindness, prevention of, 88
  Bromides and barbiturates, 453
  Carbachol and its antidote, 636
  Cave canem, 375
  Chicken-pox, congenital, 490
  Childhood, Archives of Disease in, 669
  Children, handicapped, care and teaching of, 599
  China, scientific co-operation with, 89
  Congenital defects and rubella, 635
  Czechoslovakia after liberation, 916
  D.D.T., toxicology of, 338
  Dehydration, ritual, 881
  Dentistry: A profession fully grown, 375
  Diasone in tuberculosis, 20
  Digitalis, new theory of action of, 523
  Dimethyl phthalate as an insect repellent, 705
  Doctors in hot print, 339
  Encephalitis in rubella and measles, 417
  Episiotomy, 192
  Fibrositis, 775
  Fluorescent guide to local circulation, 740
  Food control, 740
  Gramicidin, Soviet, 303
  Haemorrhage, diagnosis of, in man, 812
  Health of London, 125
  —— research in industry, 125
  Heart in rheumatoid arthritis, 636
  —— injury, 670
  Herpes zoster, 52
  Horror camp, 813
  Hospital almoner, 417
  —— meals, 599
  Housing the Royal Colleges, 88
  Hypoglycaemic fatigue, 881
  Inanition, problems of, 269
  India: Organization of research, 374—Anti-malarial measures in, 489
  Industry, sickness among women in, 523
  Infants, accidental suffocation of, 524
  Leprosy: "Asiaticocide" in, 338—Fiji leper settlement, 562—In the British Empire, 847
  Livestock fertility, 19
  Malaria: Arsenic in treatment of, 19; correction, 70—Terminology in, 88
  Medical missions, 303
  Medicine, Canadian: Scottish influence on, 339
  Mental health, united front for, 418
  —— hospital, 670
  Methyl bromide poisoning, 882
  Muscle necrosis and infection, 846
  Neurone and mind, 157
  Nicotinic acid deficiency, detection of, 561
  Old age, lonely, 525
  Ophthalmology: Non-magnetic intraocular foreign bodies, 228
  Pa Ping or barium poisoning, 775
  Paediatrics, planning in, 705
  Patulin, pharmacology of, 915
  Penicillin, new ways of giving, 227

Annotations (continued):
- Pharmaceutical Society, research at, 418
- Phi[illegible]opocial po[illegible]
- Pneumokoniosis, suspected, of graphite workers, 916
- Postgraduate training for Service M.O.s, 562
- Psychiatrist and psychologist, 229
- Psychiatrists, training of, 302
- Puberty, precocious female, 268
- Road accidents, 812
- Rollier and sunlight, 525
- Sanitary Conventions, new international, 158
- Schizophrenic testis, 453
- Senile offender, 846
- Sex hormones for melancholia, 706
- Shock therapy and conditioned reflexes, 191
- Silicosis in [illegible] scalers, 524
- Smoke: The smoke enemy, 490
- Streptomycin, a new antibiotic, 706
- Tension in tuberculous cavities, 52
- The question is . . . , 600
- Throat, clearing the, 561
- Thymectomy for myasthenia gravis, 454
- Trichinosis, a test for, 489
- Tuberculosis: Is it spread by dust? 302
- Tumours, intrathoracic nerve, 229
- Vibrating tools, clinical effects of, 741
- Visibility, conditions for good, 599
- Vitamin B: B vitamins and hard work, 191
- —— C, human requirements of, 6[illegible]0
- Walter and Eliza Hall Institute, 20
- War and the American birth rate, 453
- Wartime research in dairying, 813
- "Wound shock," treatment of, 51
- *X* rays in intestinal obstruction, 915

Anthrax, cutaneous, treated with penicillin (A. M. Abrahams), 771.
Antibiotics from plants (annotation), 776
Antibodies, estimating, 244
Antiseptics, intestinal (annotation), 157
Aphorisms, medical, 470, 544, 618
Appendicitis: Sign for acute retrocaecal appendicitis, 61—Carcinomatosis simulating (Arwyn Roberts), 153—"Grumbling appendix," 431
APPLEBAUM, I. L.: Observations on serum amylase in mumps, 603
Appointments, 126, 171, 205, 353, 430, 502, 540, 541, 686, 720
Argentina, study of cancer in (book review), 224
Angioma, cavernous, Dupuytren's contracture and, 544
Argo, Lieut.-Col. Gavin Alexander Elmslie, death of, 538
ARMATTOE, Raphael E. G.: *The Swiss Contribution to Western Civilization*, 225
Armstrong, Lieut.-Col. John Dennis Francis, death of, in Burma, 29
—— J. R.: *Bone-grafting in the Treatment of Fractures*, 631—Treatment of supraspinatus tendinitis, 688
ARNOLD, M. H. M.: Urea in diet of cows, 127
Arrhenoblastomata, 420
Arsenic: Mites, asthma, and (leading article), 18—In treatment of malaria (annotation), 19; correction, 70—Intravenous, in treatment of anginous forms of glandular fever, with notes on clinical and laboratory diagnosis (K. Shirley Smith and Trevor A. Shaw), 581 (O)
Arsenotherapy, jaundice during (B. Green), 187
Arterial disease, 208
—— injuries (annotation), 376
Arthritis: In meningococcal infections (W. P. Boger), 382—A case of, 652—Prostigmin in, 792—And allied conditions (book review), 842
—— gonorrhoeal, 642
—— osteo-: Bismuth for, 104—Mono-articular osteo-arthritis of hip treated by acid injection (W. Grant Waugh), 873 (O)
—— rheumatoid: A difficult case, 208—The heart in (annotation), 636—Fibrous nodules in, 757
Ascariasis, treatment of, 244
Aschaffenburg, Gustav, death of, 647
Ascites, hepatic enlargement with, in children ([illegible]. L. McFarlane and W. J. Branday), 838 (O)
ASHERSON, N.: Chronic otorrhoea, 677
"Asiaticocide" in treatment of leprosy (annotation), 338
ASSINDER, Eric W.: Shall we nationalize medicine? 5[illegible]
Association, British Medical: The Representative Meeting (leading article), 668—Presidency (annotation), 669

SELLORS, T. Blanchard: Infant deaths, 607
Seminological laboratory, 652
Serum, syringes, and jaundice (leading article), 810

SERVICES:
  Appointments, 29, 65, 166, 203, 240, 279, 311, 348, 388, 425, 498, 538, 574, 614, 646, 683, 716, 824, 929
  Awards, 29, 98, 132, 240, 279, 348, 388, 425, 467, 498, 538, 574, 614, 646, 683, 716, 787, 824, 859, 929
  Casualties in the Medical Services, 29, 65, 98, 132, 166, 203, 240, 279, 348, 388, 467, 498, 538, 574, 614, 683, 754, 787, 824, 859, 890, 929
  Civil Defence: Awards to M.O.s, 419
  Commended, 279
  Cross of Merit (with Swords), 132
  Deaths in the Services, 29, 65, 348, 538, 683, 716, 929
  Died, 311, 388, 538, 614, 754, 787, 890
  —— as prisoner of war, 167
  —— from enteric fever in India, 929
  —— from injuries, 203
  —— in Burma, 29
  —— in Hong Kong while a P.o.W., 929
  —— in Germany as the result of an accident, 929
  —— in hospital in India, 98
  —— in Italy, 132
  —— on active service, 65, 311, 388
  —— of wounds, 388, 538, 754
  —— on service, 29
  Efficiency Decoration of the Territorial Army, 166, 574, 890
  Freed by U.S. Forces, 574
  George Cross, awarded posthumously to Capt. J. R. O. Thompson, 240
  Killed accidentally, 388, 574, 890
  —— by enemy action, 98, 614, 787
  —— in action, 240, 348, 388, 574, 683, 929
  —— —— previously reported missing, now presumed killed in action, 538, 929
  —— on active service, 240, 890
  —— as result of air accident while a prisoner of war, 538
  Legion of Merit, 132
  Liberated, 683
  Mentioned in dispatches, 65, 98, 132, 166, 203, 240, 311, 348, 388, 498, 538, 614, 646, 683, 716, 929
  Missing, 132
  —— presumed killed, 167, 683, 754
  —— wounded, 467
  Midwives, 65
  Navy: Dental units for, 425—Medical Compassionate Fund, 574
  Order of the Nile, 279
  —— Polonia Restituta, 890
  —— Star of Nepal, 574
  Prisoners of war, 98, 132, 167, 203, 614
  —— —— repatriated, 132, 467, 574, 683, 859, 897
  —— —— safe and well in Rangoon, 787
  Soldiers' Medal (U.S.A.), 574
  Victoria Cross posthumously awarded, 388
  Wounded, 65, 98, 132, 240, 388, 467, 499, 538, 683, 787, 929

"Structural" instead of "organic," 246
Struthers, J. A. (and Andrew J. Shinnie): Tribute to Gilbert Orme, 646
—— R. R.: Infant welfare in liberated countries, 817
Strychnine, sensitiveness to, 140
Stuart-Harris, C. H.: Influenza epidemics and the influenza viruses—I, 209 (O); II, 251 (O); leading article, 266
Stungo, Ellis: Prisoner-of-war mentality, 306
Sturdee, Frederic Herbert, obituary notice of, 313
Suction apparatus, two pieces of (P. F. Jones), 447
Sudanophobic units, 245
Suffocation, accidental, of infants (annotation), 524
Sugden, F.: A protective for minor burns, 355

Sulphonamides:
  Administration per rectum, 244
  Burns, sulphonamides for, 282
  Dosage: And method of injection, 68—Prolonged use of minimal doses, 680, 750
  Dysentery, Sonne, sulphanilylbenzamide, sulphanilylamidobenzamide, and succinyl sulphathiazole, in chemotherapy of (R. Swyer and R. K. W. Yang), 149 (O)
  Impetigo, treatment of: the virtues of calamine liniment and some minor drawbacks of local sulphonamide therapy (Mary S. Smith and E. Colin Jones), 699 (O); correspondence, 853
  Kidney: lesions due to (leading article), 845
  Lactation and, 503
  Local therapy, 830
  Lozenges: Two school outbreaks of streptococcal throat infection. Effect of sulphonamide lozenges in carriers (R. L. Vollum and G. S. Wilson), 545 (O)
  Marfanil, pharmacology of, 508

SULPHONAMIDES (*continued*):
Measles, sulphonamides in, 567, 640, 680, 713, 781
Meningitis, acute; serotherapy and chemotherapy in treatment of (R.S.M.), 378
—— pneumococcal, complicated by internal hydrocephalus, treated with penicillin after sulphonamides (R. E. Rewell), 119
Otitis media: Sulphonamide therapy in, 422, 567, 617, 640—Masking effect of sulphonamides in (R.S.M.), 493
Pastilles in the oral cavity, 284
Pharmacology of, recent work on (Frank Hawking) 505 (O)
Promanide (promin), pharmacology of, 508
Promizole, pharmacology of, 508
Puerperal fever, ineffectiveness of sulphapyridine and successful action of sulphadiazine in a case of (A. Fry), 557
Pus, sulphonamides in, 786
Reticulo-endothelial system in sulphonamide therapy (book review), 518
Sulphadiazine: Solubility of, 274—And measles, 567
Sulphaguanidine, pharmacology of, 508
Sulphamerazine: A new sulphonamide (leading article), 155; correspondence, 236, 274—Pharmacology of, 508
Sulphamezathine: In acute meningitis, 379—Pharmacology of, 508
Sulphanilamide lozenges, prophylaxis of respiratory tract infections with (A. F. Hayden and Joseph W. Bigger), 81 (O)
Sulphonamide-resistant-penicillin-sensitive (Arnold Alcock), 735
Sulphapyrazine, pharmacology of, 508
Sulphasuxidine, pharmacology of, 508
Sulphathalidine, pharmacology of, 508
Ulcers, tropical, sulphonamides and (H. Mina), 369
Urinary disease, sulphonamides and penicillin in (R.S.M.), 674
See also Chemotherapy

SUMMERS, T. Collyer: Illuminated electrode for retinal detachment operation, 48—Eyesight of industrial workers, 604
Supraspinatus tendon, calcification of, 468, 652, 688
Suprapubic plate, a metal (W. Pearce), 912

SURGERY:
Abdomen: Spinal analgesia in penetrating wounds of, 129—Surgery and anaesthesia in war woun of (S. O. Aylett and A. F. Alsop), 547
Bassini operation, 458
Drainage, use of synthetic materials for (Stewart Mann), 84
Ductus arteriosus, patent, observations on ligature of (John B. Hunter), 731 (O)
Eye. *See* Ophthalmology
Facial reconstruction (book reviews), 121
Haemorrhage, intracerebral, surgical treatment of (leading article), 156

PULMONARY ACARIASIS: A POSSIBLE CAUSE OF ASTHMA

BY

E. SOYSA, M.B.Lond., M.R.C.P.Ed.
Major, C.M.C.; Medical Specialist, Ceylon Army Command

AND

M. D. S. JAYAWARDENA, L.R.C.P.&S.Ed., L.M.S.Ceylon
Capt., C.M.C.; Medical Specialist, Ceylon Army Command

(Reported from a Military Hospital in the South-East Asia Command)

During the past two years we have observed a remarkably heavy incidence of bronchial asthma among patients admitted to this hospital. Investigation resulted in the following preliminary observations:

1. A certain proportion of asthmatic patients showed a high degree of eosinophilia, ranging from 40% to over 80%.
2. These cases rarely gave a previous history or family history of asthma or other allergic manifestation.
3. The existence of alimentary parasitism, a common tropical cause of eosinophilia, was excluded by the usual pathological tests.
4. The response to treatment by antispasmodics, vasodilators, iodides, opiates, and other sedatives, autohaemotherapy, and, in severe cases, oxygen by inhalation and by subcutaneous administration, intravenous adrenaline, lumbar puncture—if of temporary benefit to the patient, and even dramatic in status asthmaticus—was unsatisfactory as regards more permanent control of the condition

Despite relief from symptoms, the eosinophilia persisted, and the patients were returned to duty, sometimes in a lower medical category, but mostly to be referred back again and again to hospital with recurrences of asthma, until their ultimate disposal was decided by a medical board who pronounced them unfit for further military service. For the period June, 1942, to June, 1944, bronchial asthma was responsible for 48% of respiratory cases and 21% of all cases invalided out of the Army through the medical division of this hospital.

There seemed no alternative disposal for these cases at the time, and when the subject was discussed at a meeting of the Clinical Society of this hospital about ten months ago, Major T. R. Jansen, C.M.C., drew our attention to a refractory case of asthma in a civilian patient with massive eosinophilic leucocytosis which had been investigated by the Civil Medical Entomological Department. This case had shown the presence of mites in the sputum, and the patient had made a remarkable recovery on treatment by administration of pentavalent arsenic. This brought to our notice the research being carried out at the Ceylon Entomological Department by Carter, Wedd, and D'Abrera, who have since (1944) published an important paper on their preliminary observations on the occurrence of mites in human sputum and their possible significance. These observers have recovered from the sputum of 17 out of 28 patients suffering from respiratory complaints various types of mites, including species of the genera *Tyroglyphus, Tarsonemus, Carpoglyphus, Glyciphagus,* and *Cheyletus.* These mites were species commonly present in stored products, dust and debris of houses, shops, and stores, etc. Arsenical treatment was found to reduce the numbers of mites in the sputum and, in three cases with eosinophil counts of 38%, 42%, and 66%, to decrease the eosinophilia, with improvement in the respiratory condition. That the work of Carter, Wedd, and D'Abrera constitutes a significant advance in the study of the pathogenesis of certain respiratory disorders seems evident to us from their preliminary report and from the application of their methods of investigation to the study of a series of cases of asthma with marked eosinophilia among soldiers under our observation.

Investigations

Our own investigations, which make no claim to completeness in scope or detail, were prompted by a search for some effective means of control over the number of asthmatic cases being invalided out of the Army, and were directed chiefly towards the aetiological significance, if any, of occupation and environment in relation to the precipitation of this asthmatic syndrome, and towards the therapeutic merits of arsenic in effecting a durable degree of recovery that might enable these asthmatic soldiers to be returned as fit for duty. Our series of cases comprises, up to the present, Ceylonese soldiers from various regimental units who were admitted to hospital with asthma associated with an eosinophilia of over 4,000 per c.mm. The patients were kept under observation in a special ward with facilities for careful supervision of the examination and treatment carried out during this investigation. Discharge from hospital was decided, not by the clearing up of the asthmatic condition alone, but by the return of the eosinophil count to a satisfactory level.

Each patient's history was carefully scrutinized with special reference to any pre-existing personal or familial tendency to allergic diathesis as might be indicated by manifestations of hay-fever, urticaria, eczema, or migraine, in addition to asthma itself; pulmonary tuberculosis and other respiratory diseases; cutaneous and intestinal affections attributable to parasitic infestation; and blood diseases. Special attention was directed towards the patient's occupation and environment in a search for such factors as might expose him to inhalation of a mite-laden atmosphere.

Pathological data were collected from investigations which included the following: (1) Examination of blood for leucocytosis, eosinophilia, and alterations in the erythrocyte sedimentation rate. Differential counts were carried out daily by the method of 1,000-cell counts. (2) Examination of faeces repeatedly for ova, cysts, parasites, and Charcot-Leyden crystals that might indicate intestinal infection or infestation. (3) Examination of sputum for *B. tuberculosis* repeatedly and by special technique for mites.

The examination of sputum for mites is a prolonged and tedious procedure involving special methods of preparation of the specimens and rigid precautions against contamination of the material by mites from extraneous sources. Twenty-four-hour specimens of sputum were collected direct in rubber-stoppered flasks and large test-tubes which had been specially prepared by thorough washing and flushing in running water to ensure adequate decontamination; the stoppers, which had been similarly decontaminated, were removed by the patient and held in his hand just long enough to permit the expectorated sputum to be discharged into the vessel, which was immediately re-stoppered tightly. The preparation of the sputum for examination was carried out according to the method described by Carter, Wedd, and D'Abrera.

> "The fresh sputum was treated in the first place with an equal quantity of 1% potassium hydroxide; this was shaken and allowed to stand until the muco-purulent material had disintegrated. After a few hours, when the mixture had become more or less clear,

from 5 to 10 drops of Loeffler's alkaline methylene blue were added and the solution again shaken. Formalin sufficient to give a 10% concentration was then introduced and the mixture left until next morning (18 to 24 hours). The mixture was then centrifuged and the supernatant fluid drawn off; the deposit was examined under a binocular microscope."

Throughout this entire procedure scrupulous precautions have to be adopted against contamination of the sputum with mites from outside sources The material has to be systematically searched under the microscope for the presence of mites, and the examination of a few smears, as for tubercle bacilli, is not sufficient for this purpose. The amount of labour and time involved in this procedure will be evident.

For radiological study of the course of the cases, skiagrams of the lungs were taken on admission of each case to the ward and repeated before discharge. Some of the patients were similarly examined during the course of treatment and the progress of their pulmonary condition observed by means of the altering appearances of the serial skiagrams.

A daily clinical check was maintained on the patients throughout the period of observation with the object of noting any relation between the degree of intensity of the asthmatic condition and that of the eosinophil count. While such clinical features as temperature, pulse rate, or eosinophil count could be accurately measured and charted, signs and symptoms of the nature of expiratory dyspnoea, prolonged expiration, or sibilant and sonorous rhonchi obviously do not lend themselves to similar methods of recording. However, an attempt was made to record the variations in the clinical course of each case by means of a block graph which served to provide a rough chart of the relative severity of the asthmatic condition from day to day.

Treatment was carried out in two stages: first, with routine anti-asthmatic remedies, and thereafter with specific therapy, the variations in response being recorded by means of the eosinophil chart and the clinical block graph. Routine treatment consisted of the pharmacopoeial "mist. asthmatica," comprising the usual remedies—potassium iodide, tincture of belladonna, and tincture of stramonium—but excluding any arsenical preparation. Additional measures for relieving severe dyspnoeic attacks—e.g., ephedrine, adrenaline, pituitrin—were employed whenever necessary, particularly when sleep was disturbed by nocturnal paroxysms. Specific treatment consisted in the oral administration of pentavalent arsenic. Stovarsol was the drug used at first, in the form of 0.26-g. tablets containing 27% arsenic. At an early stage of the investigation supplies of this drug ran out, and we decided to substitute carbarsone until it was again available. Carbarsone was administered in 0.25-g. tablets containing 28.85% arsenic. The daily dosage employed was one tablet twice daily of one or other of these preparations. No special dietary restrictions were imposed during treatment, the "ordinary diet" of the hospital regime being allowed in every case except during febrile periods, when "milk diet" was substituted.

Case Records

Our present series comprises 30 patients, representing various military units: Army Service (10), Engineers (5), Artillery (6), Infantry (2), Medical Corps (3), Signal Corps (1), Military Police (2), Pioneers (1). For considerations of space detailed case histories are not reproduced here, but a tabulated analysis of the more significant positive findings is appended instead, together with notes on the aetiological, clinical, pathological, and therapeutic observations recorded during our investigation.

Tabular Analysis of Cases

Case No.	Age (Years)	Service (Mths.)	Duration of Asthma (Prior to Admission)	Occupation, Duties, Environment (Prior to Onset of Asthma)	Leucocyte Count		Eosinophil Count				Sputum Report	Treatment	
					Initial	Final	Initial		Final				
					Per c.mm.	Per c.mm.	Per cent.	Per c.mm.	Per cent.	Per c.mm.		Routine (Days)	Arsenical (Days)

Actiological Observations

The ages of the patients ranged between 18 and 42 years, and their periods of military service varied from 3 months to 5 years. With the exception of Nos. 14 and 19, who had suffered from lobar pneumonia, none of the patients gave a history of having been affected by any respiratory ailment other than that under investigation. Two patients (Cases 5 and 21) had been treated for mild attacks of dysentery of unspecified nature. None of the others gave a history of any intestinal infestation or of any cutaneous affection that might be associated with eosinophilia. Malaria figured in the past histories of 7 patients (Cases 5, 11, 12, 14, 16, 20, 22), but not in any prominent degree. There was no evidence of any tendency to an allergic state prior to the onset of asthma, which in all cases but three (Cases 7, 9, 27) had occurred after enlistment in the Army. The interval between enlistment and the onset of asthma in the other cases varied from 2½ to 35 months.

There was no indication of any familial tendency to allergic diathesis or to any respiratory disease or blood disorder in the case histories, with the exception of that of Case 19, where it was stated that one brother suffered from chronic bronchial asthma and another from early pulmonary tuberculosis, and that of Case 13, where a sister was said to be tuberculous.

Significant aetiological information was collected from an inquiry into the nature of the occupation and environment of the patients before the onset of asthma. No fewer than 25 of these 30 patients either had been engaged in orderly or sentry duties in ration stores, in loading or transporting rations, or had been quartered in the neighbourhood of ration stores. Of the remaining cases Nos. 2, 7, and 19 had worked in other dusty stores where linen, clothing, boots, pack articles, and miscellaneous goods of various descriptions were handled, while the carpenter (Case 16) had obviously been exposed to inhalation of sawdust and the tinker (Case 8) had worked in a dusty petrol service store.

Clinical Observations

The onset of the condition was invariably slow and insidious, with an intermittent dry cough which became progressively more frequent and troublesome, particularly at night. Gradually the patients began to suffer from spells of expiratory dyspnoea with wheezing. These attacks, though generally mild and intermittent at first, became more and more frequent, causing increasing loss of sleep with a feeling of lassitude, malaise, and asthenia in the mornings, leading to a gradual impairment of general health and physical fitness. The duration of the asthmatic condition varied from 2 weeks to 3 years, and the constitutional symptoms rarely troubled the patient before his asthma had lasted about a month.

On admission to hospital the clinical picture was that of the usual symptom-complex of asthmatic bronchitis—cough with expiratory dyspnoea, hyperresonance of the lungs, prolonged expiration with sibilant and sonorous rhonchi audible all over the chest, and occasional leathery rales at the pulmonary bases. The sputum in most cases was scanty and viscid and never blood-stained; in a few cases there was no expectoration at all. One patient (Case 1) coughed up fairly copious quantities of stringy, tenacious, mucus during the early stages, and felt considerably exhausted by his frequent and strenuous efforts at expectoration. Only 5 patients (Cases 3, 5, 7, 12, 28) showed a febrile temperature; but pyrexia was not a prominent feature of these cases, the temperature ranging from 99 to 101° F. and lasting from two to five days.

None of the patients showed signs of any cardiovascular disorder, enlargement of the spleen or liver, or cutaneous affection, such as psoriasis, scabies, etc. Appetite, digestion, and alimentary function were generally unimpaired, except for a mild attack of intercurrent enteritis in Case 3. No such allergic manifestation as hay-fever, urticaria, eczema, or migraine occurred in the clinical course of any of the cases.

Pathological Observations

Haematological examination showed a remarkably constant eosinophilic leucocytosis in the series of cases, with massive eosinophilia in many of them. The total leucocyte count ranged from 10,200 to 37,000 per c.mm., while the eosinophil concentration varied between 33% and 81%. It is from the absolute leucocyte count that the blood picture can best be appreciated. While there was no appreciable alteration in the total numbers of polymorphonuclear cells and lymphocytes, there was an enormous increase in the number of eosinophils, ranging from 4,484 to the massive concentration of 27,010 per c.mm. In assessing the degree of eosinophilia, therefore, the absolute count was used as the criterion of our initial and final records, but a percentage calculation based on daily 1,000-cell counts was employed for charting the course of each case. The eosinophils were mature cells that stained well and showed no abnormality. In a few cases the eosinophil count showed a sudden drop to a relatively low level without any special treatment, but only to rise after a brief remission. A good example of such a spontaneous temporary remission was patient No. 22, who on a previous admission to hospital recovered from his asthma with a sharp drop in his eosinophil count from 65% to 5% and was discharged, but was readmitted later with a recurrence of asthma and an eosinophilia of 33%. This case taught us the need for keeping such patients long enough under observation to decide whether the remission is temporary or not. In a few cases we found that asthmatic signs and symptoms were mild, or even temporarily in abeyance, while massive eosinophilia persisted. But in general there was a recognizable parallelism between the eosinophil content of the blood and the intensity of the asthmatic condition.

With the exception of a mild degree of secondary anaemia in a few cases there was no abnormality in the erythrocyte count or haemoglobin content of the blood. The erythrocyte sedimentation rate generally showed no appreciable deviation from the normal, apart from a few recordings of a slightly accelerated rate that was attributable to associated bronchitis.

The sputum did not show red blood cells, acid-fast bacilli, or any specific organisms on routine microscopical examination, but eosinophil leucocytes were sometimes observed. Mites of either *Tyroglyphus* or *Tarsonemus* were found in 11 out of 21 cases whose sputum was examined by the special technique described by Carter, Wedd, and D'Abrera. This procedure—a tedious one involving prolonged and patient searching through a comparatively large mass of material in which the mites may rarely be present in more than scanty numbers—was a limited application in the circumstances. Some of the examinations lasted as long as five days (besides the two days or more needed for collecting and preparing the specimens) before mites were detected. Search was abandoned in cases in which no mites were seen within this period. There was rarely time for the examination of more than a single specimen of sputum from each patient. It was found that the chances of detecting mites seemed most favourable within three or four days of starting arsenical therapy. The scanty numbers of mites observed in our cases—rarely more than one or two—may be partly due to the fact that search was rarely continued after the first mite was detected in each specimen of sputum. In Case 11, however, about 14 mites were found in a specimen collected on the third day of carbarsone treatment.

Repeated examination of faeces showed mild infestation with *Ancylostoma duodenale* in Case 5; *Ascaris lumbricoides* in Cases 18 and 19; *Trichuris trichiura* in Cases 11, 12, and 18; *Blastocystis hominis* in Cases 4, 6, and 9; and *Trichomonas faecalis* in Case 12. Appropriate anthelmintic treatment was administered, but this produced no reduction in the eosinophil count, which in one of the roundworm cases actually rose afterwards. The urine showed no abnormality to routine chemical and microscopical tests, and there were no clinical indications for any special investigations such as for detection of mites in the urine.

Radiological Observations

Analysis of the radiological findings before treatment showed the frequent appearance of a pronounced catarrhal reaction of the finer lung markings, resulting in diffuse linear striations of a strikingly even and symmetrical distribution in both lung fields; this was suggestive of an acute inflammatory process resulting in a bronchitic or bronchiolitic reaction rather than of tuberculous infiltration. In addition there was a remarkable mottled effect produced by small, discrete, ill-defined spots disseminated throughout both lung fields; they were usually more evident in number and size in the hilar and basal zones. The hilar shadows often showed increased density. The combined effect of the shadows produced by the accentuated finer lung markings and by the mottling resulted in a hazy, ground-glass appearance, which proved to be so characteristic of the condition that several of the later cases received the concise radiological diagnosis, "Appearances of eosinophil lung present." These appearances seemed to be displayed best in the earlier cases, but were evident even where the asthma had lasted from 1 to 3 years (Cases 19, 9, 7). The chronic cases, however, more often showed appearances of certain associated changes such as chronic bronchitis, pleural thickening, emphysema, or prominence of the pulmonary artery. The mottling was not evident in a few cases the clinical condition of which was mild.

Re-examination of the lungs after arsenical treatment showed a remarkable change in the lung picture. The nodular opacities causing the mottling had disappeared and the linear striations had similarly disappeared or had subsided in intensity. The clearness of the lung parenchyma was in striking contrast to its original hazy appearance.

Therapeutic Observations

Each patient acted as his own therapeutic control by undergoing a course of routine treatment for asthma before being given arsenic. This stage of treatment varied from 10 to 50 days, some of the patients having already been under such treatment in other wards of the hospital before being referred to us. During routine treatment the eosinophil count dropped in Cases 4, 5, 11, 12, 14, 16, 18, and 21, and rose in Cases 1, 2, 7, 8, 13, 15, and 20, remaining at a relatively stationary level in the others. The most marked fluctuations were a sharp drop from 80% to 18%, with a subsequent rise to 52%, in Case 11; a drop from 60% to 28%, with a rise to 50%, in Case 12; a rise from 35% to 70% in Case 15; and a rise from 25% to 60% in Case 20. The clinical response to routine treatment was generally unsatisfactory, most of the patients showing no improvement, others obtaining only temporary relief from their asthma. In Cases 2, 8, 10, 16, and 18 adrenaline injections were required to alleviate severe asthmatic paroxysms, mostly nocturnal; 8 injections of adrenaline m. vii with pituitrin 0.5 c.cm. had to be given in Case 16. Only Cases 9 and 12 showed any appreciable relief from routine treatment.

The stage of arsenical treatment varied in duration from 6 to 33 days, two tablets of carbarsone or stovarsol being administered daily. The response to arsenic was uniformly good and sometimes dramatic. Patient No. 7, who had suffered from asthma for 3 years, obtained no relief during 48 days of routine treatment, while his eosinophilia rose from 56% to 65%; from the very start of carbarsone treatment his eosinophil count dropped rapidly, and he was free from asthma in 3 days; he needed only 9 days' treatment with 18 tablets of carbarsone to complete his cure. Equally dramatic was the response in Case 21, in which the eosinophils dropped from 62% to 3%, with complete relief from asthma and restoration of pulmonary radiolucency, after 12 tablets of carbarsone in 6 days. Cases 1 and 5 completed treatment in 10 days with 20 tablets—of stovarsol in the former, and of carbarsone in the latter. Most of the patients showed a gradual haematological response to arsenic, Case 2 being a typical example; but alleviation of clinical symptoms was comparatively rapid in all cases. Several patients had exacerbation of symptoms between the third and sixth days of arsenical treatment. Cases 2 and 8 developed status asthmaticus on the fifth and fourth days respectively; the former was relieved by the continuous adrenaline injection technique of Hurst, but the second was more refractory and required lumbar puncture, which resulted in almost instantaneous control of the condition. The alarming manifestations in these two cases led to some diffidence about arsenical treatment on the part of other patients in the ward, and one was found secreting his tablets in a hollow tooth; thereafter the drug was administered in solution to prevent patients shirking treatment, which might have accounted for the delayed response in some of the cases. The criterion of cure was not the control of the clinical condition (which was generally effected in 7 to 10 days) but the reduction of the eosinophil count to a satisfactory level, and arsenic therapy was continued accordingly. There was no appreciable difference between carbarsone and stovarsol as regards the clinical response and control of asthmatic symptoms; but the former generally produced a more satisfactory and prompt haematological response, while the delayed reaction of the latter drug in this respect entailed a more prolonged period of medication. Both drugs were well tolerated, considering that several patients were under treatment for over 20 days.

Up to the present (over 9 months since the first patient was discharged from hospital) no recurrence of asthma has been reported in any of these patients by their regimental medical officers, while several who have been re-examined have shown a normal haematological picture.

Conclusions

This series represents a distinct group of asthmatic cases with marked eosinophilic leucocytosis and characteristic radiological appearances of the lungs. They showed no familial or pre-existing susceptibility to the disease. The response to orthodox methods of treatment was strikingly unsatisfactory in comparison with the remarkable control produced by pentavalent arsenical therapy.

The syndrome appears to correspond with that described in India by Frimodt-Möller and Barton (1940) as "a pseudo-tuberculous condition associated with eosinophilia," by Weingarten (1943) as "tropical eosinophilia," by Treu (1943) as "pseudo-tuberculosis of the lungs with eosinophilia," by Simeons (1943) as "benign eosinophile leukaemia," and by Chaudhuri (1943) as "eosinophil lung." Similar cases had been reported from Ceylon by Carter, Wedd, and D'Abrera (1944), from Egypt by Parsons-Smith (1944), and from the United States (in an ensign eight months after his return from India) by Emerson (1944).

The duration of asthmatic symptoms in our cases varied between 2 weeks and 3 years. The symptomatology differed from some of the cases reported by previous observers in the absence of splenic enlargement and the infrequency of pyrexia, while the occurrence of bronchial asthma in every one of our patients was due to the fact that the investigation was particularly directed towards this condition.

Diagnosis.—The differential diagnosis involves the exclusion of pulmonary tuberculosis, pneumoconiosis, and bronchomycosis as causes of the respiratory manifestations, and of helminthiasis, cutaneous infestations, and certain haematological disorders in relation to the eosinophilia.

Pulmonary tuberculosis is negatived by the absence of *B. tuberculosis* in the sputum, by the haematological findings, by the lack of clinical evidence, and by the remarkable response to arsenic therapy. The diffuse and symmetrical infiltration seen in the skiagrams of the lungs is alien to tuberculosis, though the mottled appearance due to the disseminated nodular opacities may simulate miliary tuberculosis; but the spots are smaller and less clearly defined, and the linear striations more accentuated, than in miliary tuberculosis.

Pneumoconiosis was a not unlikely possibility in our patients, whose lungs showed a suggestive radiological picture after a definite history of exposure to a dusty environment. But the mottled effect and the absence of diffuse fibrotic changes in the skiagrams, the rapid restoration of normal pulmonary radiolucency after arsenic therapy, together with the fact that eosinophilia is not pathognomonic of pneumoconiosis, serve to eliminate this condition from the diagnosis.

Bronchomycosis, which might have been suggested by some of the skiagrams, was excluded by the absence of fungal hyphae or blood in the sputum, and by the therapeutic response, not to potassium iodide, but to arsenic.

Helminthiasis might play a part in the production of eosinophilia and even in producing transient localized pulmonary infiltrations as in Loeffler's syndrome, where it has been presumed that the migration of helminth larvae through the lungs may be responsible for these changes. Negative evidence of any significant helminthic infestation precluded these factors in our cases.

The possibility of cutaneous infestation, psoriasis, and eczematous and other dermatoses as causative factors in eosinophilia did not arise in any of our cases.

Eosinophilic leukaemia—a rare blood disorder associated with massive eosinophilia in which the leucocytes show evidence of immaturity in size and form—was excluded by the absence of any such abnormality in the cells seen in our cases, and by the absence of splenomegaly. Simeons has remarked that many of the eosinophils show evidence of having reached a more advanced stage of development in nucleation and lobulation.

Such anomalies as "idiopathic eosinophilia" and "hereditary eosinophilia" can be excluded on aetiological, clinical, and radiological grounds. Mite infestation might provide a satisfactory explanation of the former condition where haematological changes might be the sole reaction.

Spirochaetal agency might be suggested by the specific response to arsenic. The pre-eminent virtues of arsenic as a spirochaeticide need not preclude its therapeutic efficiency in other conditions any more than in the case of potassium iodide, mercury, or bismuth. Syphilis is not suggested in this condition by the clinical, radiological, or haematological findings. Serological tests by previous workers have provided no evidence of a syphilitic pathology in this syndrome, apart from coincidental infection in a few cases. Postulation of some obscure spirochaetal agency on grounds of the therapeutic reaction must await satisfactory confirmation. Meanwhile, the discovery of mites in the sputum of these patients is a positive factor upon which further inquiry and investigation can be based.

Treatment.—The eminently successful and often dramatic response of this syndrome to arsenical therapy is now well established. This was first observed by Weingarten in 1936, through one of his cases contracting syphilis; after four injections of neoarsphenamine the patient's subjective symptoms vanished and his eosinophilia showed a remarkable drop. In 1941 Treu obtained similar results by the trial of acetylarsan intramuscularly. Simeons used mapharside in 10% calcium gluconate with equal success. Since then other observers have confirmed the excellent therapeutic response—clinical, haematological, and radiological—to arsenic in this condition. Our present series of cases was treated by oral administration of carbarsone or stovarsol with a view to determining the value of such measures under circumstances in which facilities for parenteral therapy are not readily available, and our results justify the view that, even if the haematological response be sometimes delayed, oral treatment provides a very satisfactory means of dealing with this condition. From our experience, the period of treatment would seem to be appreciably curtailed by the use of carbarsone. Arsenic is not a new drug in the therapy of asthma. Aromatic arsenicals empirically added to asthma mixtures have given good results in the hands of the older practitioners, while more prominent success has followed the use of arsenic in organic form in recent times. The effect of this well-known parasiticidal drug in an asthmatic syndrome associated with mite infestation may well provide a possible explanation of its long-standing merits in bronchial asthma.

Pathogenesis.—The demonstration of *Tyroglyphus* and *Tarsonemus* mites in the sputum of some of our cases lends support to the discovery of Carter, Wedd, and D'Abrera already referred to. The collection and examination of sputum specimens in our series were subjected to all possible precautions against contamination by mites from extraneous sources. One other case, referred from another ward of the hospital with a mite-positive sputum report, is not included in the present series as the precautions against extraneous contamination of the sputum seemed to be of doubtful efficiency. Carter, Wedd, and D'Abrera have eliminated the possibility of the mites being derived from the mouth or nasal passages of the patients by examining several specimens of saliva and nasal washings, none of which showed mites. Controls, using distilled water without precautionary measures, were carried out at times when specimens of sputum were being collected; and vessels containing distilled water were exposed overnight in the vicinity of mite-infested patients. No mites were found in any of these controls. In all patients whose sputum contained mites the findings were confirmed by subsequent examination, while in 11 negative cases no mites were found at any time. The evidence collected by these observers strongly points to the inference that mites invade, and even breed in, the lungs and bronchi of patients, obtaining access by inhalation. We have adduced evidence to justify the inference that our patients had acquired their disability after the inhalation of mite-laden air. The majority of our cases had been exposed to dust emanating from rice and other cereals, pulses, flour, sugar, tea, coffee, cheese, dried fish, dehydrated vegetables, spices and other condiments, and various other dry rations and grocery products such as are issued in bulk through ration stores. A few patients had worked in depots where military equipment and miscellaneous articles such as linen and leather goods were stored. The frequent existence of tyroglyphid and tarsonemid mites in stores and stored products being recognized, all these patients must be regarded as having been exposed to the risk of inhalation of these mites, which were later recovered from their sputum in certain cases. Chronic respiratory disabilities are known to occur in workers exposed to inhalation of wood dust; this material is sometimes infested with fungi of various types, particularly when derived from decaying timber in dilapidated houses subject to "dry rot," and from sawdust from unseasoned woods. Mites of the genus *Glyciphagus* have been known to occur in sawdust, and this may explain the case of one of our patients, a carpenter, who had been exposed to inhalation of sawdust, chiefly from immature and unseasoned timber. In this connexion it would appear that the possibility of a similar causation in the condition that has been recently described as "bagassosis"—a respiratory affection occurring among workers in bagasse or the residue from crushed sugar-cane—deserves investigation in view of the fact that tarsonemid mites are known to occur on sugar-cane, causing serious damage to crops, while the frequency of tyroglyphid mites in sugar is notorious. In bagassosis, however, eosinophilia does not seem to occur, while spontaneous recovery from the clinical and radiological changes appears to be common. The pathogenic significance of acarine mites seems, so far, to have received but scant attention in the literature. Certain references to this subject cited by Carter, Wedd, and D'Abrera are of interest:

> "Invasion of the human alimentary and urinary tracts by tyroglyphid and tarsonemid mites has been held responsible for certain pathological effects. Various forms of dermatitis have been known to occur through mite infestation—e.g., 'grocer's itch' in workers in shops and stores where *Tyroglyphus* mites abound; 'grain itch' and 'straw itch' among those handling certain crops infested with *Tarsonemus* mites—rice and other grains, tea, sugar-cane, pineapples, etc. Cutaneous and asthmatic symptoms in mill-workers have been attributed to their handling of grain infested with the mite *Pediculoides ventricosus*. Horses fed on maize infested with *Tyroglyphus* and other mites have been reported to have sickened and died as a consequence of respiratory and alimentary disorders. Monkeys are known to harbour parasitic mites of the genera *Pneumonyssus* and *Pneumotuber* in their respiratory organs, and these mites are stated to be capable of causing serious pathological conditions."

The pathological changes underlying the present syndrome remain obscure owing to lack of knowledge as to its morbid anatomy. The condition is essentially benign, though it may run a chronic course if untreated, and the possibility of a case going to necropsy is remote, except through some fatal intercurrent complication. The views of previous observers on the possible pathogenesis of this condition have been based on certain interpretations of the haematological and radiological findings:

Frimodt-Möller and Barton have expressed the view that an allergic origin is implied by the fact that eosinophilia dominates the syndrome. Weingarten at first favoured an allergic explanation of the condition, but later decided that such an interpretation is not acceptable, and emphasized the unquestionable influence of environment as an aetiological factor. This observer has also drawn attention to the striking similarity between the distribution of the radiological mottling of the lungs and that of the bronchial tree, and considers that the mottling represents bronchopneumonic infiltration of groups of alveoli, probably caused by peribronchial lymphatic spread. Chaudhuri has suggested that a widespread pulmonary infiltration by eosinophils with large granules might explain these radiological appearances. Treu has made the observation, in reporting one of his cases in which an intercurrent pneumonia interfered with arsenical therapy but was followed by complete cure of the original condition, that the pneumonic infection might be assumed to have acted as a severe protein-shock therapy. Simeons considered that eosinophilia with the changes he has noted in the nuclei and lobulation of these cells is pathognomonic of the disease, while radiological changes in the lungs are inconstant. He has also found that injections of liver extract increase the haematological abnormality. He considers the condition identical with the "grande éosinophilie sanguinaire" of French authors.

Eosinophilia being regarded generally as the prominent feature of this syndrome, it is interesting to note that Osler has mentioned that the eosinophil count may rise as high as 53% in asthmatic patients. The view that the mottling of the lungs seen on radiological examination may be due to focal eosinophilic infiltrations obtains support from two observations—the frequent expectoration of eosinophil cells, and the concurrent disappearance of both the radiological and the haematological abnormalities after treatment. Although massive eosinophilia and radiological mottling of the lungs are frequent and dominant features in this syndrome, the view that they are essential characters of the condition remains open to question, for atypical variations lacking one or both of these features would seem possible:

In 5 of the mite-positive cases examined by Carter, Wedd, and D'Abrera the blood picture was normal; in 5 others eosinophilia of 6% to 12% was observed. We have seen spontaneous remission of the clinical and haematological condition in 3 patients, one of whom (Case 22) later returned with a recurrence, the others (not included in the present series) being still under observation. Weingarten has remarked that radiography in chronic cases shows only pulmonary changes identical with chronic catarrhal bronchitis. This was also evident in a few of our cases, particularly among patients with mild clinical manifestations. Since our investigations were started several asthmatic patients admitted to other wards of this hospital with eosinophil counts of from 3% to 15% and no characteristic radiological appearances, who have failed to respond to routine treatment, have been successfully treated with arsenic. The number of asthmatic patients discharged cured from this hospital has shown an appreciable rise, while the number of men invalided out of the Army for this condition has correspondingly declined, since the introduction of pentavalent arsenic therapy.

If the view advanced by Carter, Wedd, and D'Abrera that this syndrome may, in part at least, be explained on the basis of mite infestation of the respiratory system be accepted, the question that next arises concerns the role of the mites in the pathogenesis of the condition. Even if the asthmatic symptoms be interpreted as due to reflex irritation of a hypersensitive bronchial system, the eosinophilia does not bear explanation in these terms, and an allergic causation would seem to be the more likely explanation. German authorities, cited by Carter, Wedd, and D'Abrera, have expressed the opinion that alimentary, respiratory, and cutaneous disorders may result as allergic reactions to infestation with tyroglyphid mites. Further research is necessary, and doubtless will be forthcoming, to ascertain whether the mites occurring in the sputum of patients suffering from this syndrome are capable of producing a respiratory allergen—as, for example, some exotoxin or other secretion.

In the light of present knowledge this syndrome, which has hitherto been recognized as a fairly common tropical respiratory disease of obscure aetiology and pathology, would appear to be due, in some cases at least, to pulmonary acariasis caused by the inhalation of a mite-laden atmosphere and possibly inducing allergic reactions in the respiratory system. Although our investigations have so far concerned patients who have lived or worked in obviously mite-infested surroundings, such as ration stores, the liability to pulmonary acariasis from less evident and unsuspected sources must not be overlooked, for mites are widely distributed.

While living in an old house in Colombo, long ago, one of us (E. S.) developed asthma, which cleared up with a change of residence. Another occupant of that house was badly affected with asthma for many years. About thirty years later a medical colleague went to live in the same house, and he, too, developed asthma, which left him when he moved from there. This seems more than mere coincidence, and some obscure factor in the environment of that house—e.g., some constituent in the house dust or some particular flowers in its garden—must have been responsible for the asthma. Flowers have borne their share of blame for causing asthma over many decades. Mites are recognized pests of various cultivated plants and flowers; orchids, grown so freely in tropical gardens, and certain fragrant flowers much in vogue for personal adornment, household decoration, and temple offerings, are notable examples of this. The inducement offered by flowers to inhale their perfume has no doubt enhanced the reputation of their pollen as an asthmogenic agent. May it not be likely that mites harbouring in flowers are justly entitled to some share of this reputation?

The possible coexistence of pulmonary acariasis with other lung affections cannot be overlooked. Three cases of asthmatic bronchitis now under observation in this hospital, but not included in our present series, have shown eosinophilia with radiological evidence suggestive of tuberculous infiltration of the lungs; in one case the presence of both *B. tuberculosis* and *Tyroglyphus* mites in the sputum has been demonstrated. Mites have been found in the sputum of two cases of pulmonary tuberculosis recently examined at the Civil Medical Entomological Department of Ceylon.

In conclusion, the possibility that pulmonary acariasis may be responsible for other respiratory disorders besides asthma should not be ignored. Though our present investigations, for reasons already stated, were restricted to patients suffering from asthma, some of the cases described by previous observers as “pseudo-tuberculosis,” “tropical eosinophilia,” “eosinophil lung,” etc., have not been typical of bronchial asthma. Such cases, particularly when associated with a suspicious aetiology and resistance to orthodox therapeutic measures, might well be manifestations of pulmonary acariasis. The treatment of all such cases, whether asthmatic or otherwise, by the administration of pentavalent arsenicals is eminently worthy of consideration not only in the Tropics but anywhere that mites exist.

We wish to express our thanks to Brig. C. A. Slaughter, D.D.M.S., Ceylon Army Command, and to Col. V. H. L. Anthonisz, O.B.E., E.D., Officer Commanding this hospital, for permission to publish this paper; to Mr. H. F. Carter and Dr. V. St. E. D'Abrera for assistance in examining specimens for mites in Cases 1, 2, and 4; to Capt. W. D. Ratnavale, C.M.C., pathologist to this hospital, for supervising the remaining pathological examinations; to Major B. Chatterjee, I.A.M.C., and Capt. R. Heathcote, I.A.M.C., for the radiological examinations; to Sister A. R. Livermore for supervising the investigations and treatment in the ward; and to several colleagues on the medical staff for their co-operation in selecting cases and referring them to us for this investigation.

THE URINARY ELIMINATION OF NICOTINAMIDE METHOCHLORIDE IN SUBJECTS WITH NORMAL GUMS AND WITH ACUTE AND CHRONIC GINGIVITIS

BY

R. A. COULSON, M.S.Louisiana State, Ph.D.Lond.

P. ELLINGER, Dr.med.Heidelberg, Dr.phil.Greifswald

AND

G. A. SMART, M.D., B.Sc., M.R.C.P.
Squad. Leader, R.A.F.V.R.

(From the Lister Institute, London, and the Royal Air Force Institute of Pathology and Tropical Medicine)

The apparent similarity of acute ulcero-membranous gingivitis to pellagrous lesions of the mouth led Platt (cf. King, 1940) to suggest that nicotinic acid deficiency might play a part in the aetiology of the former condition. Subsequently King (1940, 1943, 1944) investigated the therapeutic effect of nicotinic acid and its amide on both acute and chronic gingivitis, and found that these compounds were highly beneficial. Other workers, however, have been unable to confirm these findings (Miller, Greenhut, and Roth, 1940; Ungley and Horton, 1943).

It was noted by Najjar and co-workers (1940, 1941a, 1941b, 1942) that a fluorescent pigment, “F_2,” could be obtained from the urine of normal dogs and normal human beings. The amount obtained was increased after the ingestion of nicotinic acid and several related compounds, but the pigment was absent from the urine of pellagrins and from that of dogs suffering from black-tongue. Further work (Huff and Perlzweig, 1943) suggested that “ F_2 ” was nicotinamide methochloride, but two of us (Ellinger and Coulson, 1943; Coulson and Ellinger, 1943) have shown that nicotinamide methochloride in aqueous solution was non-fluorescent, that the substance present in the urine was also non-fluorescent, that this urinary substance was identical with nicotinamide methochloride, which gave rise to fluorescent “ F_2 ” after alkalinization and transfer to isobutanol, and that fluorescent “ F_2 ” is probably a mixture of the *p*- and *o*-carbinol of N-methyl-dihydro-nicotinamide.

Before the nature of the compound had been established a method of assay for “ F_2 ” in urine which gave relative but not absolute results was developed (Coulson, Ellinger, and Platt, 1942; Coulson, Ellinger, Glock, and Platt, 1942). Recently Coulson, Ellinger, and Holden (1944) have developed a quantitative method of assay for urinary nicotinamide methochloride. This method of assay forms the basis of a convenient test to indicate the nicotinamide level of the body.

This paper, which reports part of an investigation into gingivitis in the Royal Air Force initiated by Air Marshal Sir H. E. Whittingham, Director-General of Medical Services, presents the results obtained from the estimation of nicotinamide methochloride in the urine of subjects with gingivitis and those with normal gums.

Methods

Chemical.—(*a*) During the earlier part of the investigation, the composition of “ F_2 ” or its precursor not having been determined, the method of assay which was used gave results in arbitrary units comparable with each other. (*b*) Subsequent to the identification of the precursor of “ F_2 ” the quantitative method developed by Coulson, Ellinger, and Holden (1944) was used for the assay of urinary nicotinamide methochloride. The results of the first method cannot be converted into absolute values, since other factors, such as urinary electrolyte content, which were found to influence the assay, were controlled in the second method but not in the first.

The principle of both methods of assay is as follows. Aliquot portions of urine, the excretion rate of which was known, were absorbed on a Decalso column, which was subsequently washed with water and eluted with potassium chloride. The eluate was divided into two halves, both of which were extracted with isobutanol, one after alkalinization with sodium hydroxide. The alkaline extracts were fluorimetrically compared with standards, while the neutral extracts served as reagent blanks.

Clinical.—The gums of all subjects who took part in this investigation were examined, and were classified into the following groups, described in greater detail by Smart (1944). A: Normal. B: Non-ulcerative gingivitis. C: Gums without an active lesion, but which showed evidence of past inflammation and tissue destruction. D: Chronic ulcerative gingivitis. E: Acute ulcero-membranous gingivitis and gingivo-stomatitis, (i) arising on gums which appeared to have been previously healthy, (ii) arising on gums with evidence of former inflammation or ulceration.

Experimental.—The investigations may conveniently be divided into two groups, according to the method of assay employed for urinary nicotinamide methochloride.

(i) *Those investigations in which the earlier, relative method of assay was used were carried out at each of 4 Royal Air Force stations (I, II, III, and IV)*.—A random sample from all the airmen at each station was examined. The gums of these subjects were classified into the groups described above, and each person with gingivitis, together with the next with normal gums, was selected for the purpose of the experiment. Each was instructed to collect the whole of the urine which he passed on waking in the morning, to note the time of this collection, to note the time at which the bladder was last emptied on the previous night, and to estimate the muscular energy required for the duties performed on the day preceding that on which the urine was collected. The volume of each of these specimens was measured and samples were sent to the Lister Institute for assay. This was repeated, where possible, on three successive mornings, but leave, postings, duties, etc., made this impracticable for a number of subjects. A few gave data that were either incomplete or were suspected of being inaccurate.

(ii) *Investigations on groups of subjects—R.A.F. and civilians—in which the urinary content of nicotinamide methochloride after the oral intake of nicotinamide was quantitatively determined*.—It had been found that the daily variation in the early morning urinary content of nicotinamide methochloride was so great that an attempt was made to develop a test which gave more consistent results. This was obtained by following the urinary nicotinamide methochloride content after the ingestion of a test dose of nicotinamide. Consistent results have also been obtained from 24-hour samples, but it was impracticable to collect such samples from airmen on duty or from out-patients. In preliminary experiments 200 mg. of nicotinamide was given by mouth, the urine being collected immediately before this test dose and at intervals afterwards. It was found, however, that a considerable time (over 13 hours) elapsed before the urinary nicotinamide methochloride returned to normal levels, and it was impracticable to observe the subjects for such a long period. Satisfactory results were obtained by giving a test dose of 100 mg. nicotinamide by mouth and determining the amount of the methyl derivative eliminated in the urine during the following 7 hours, at the end of which period the level had returned almost to normal. This test was carried out on two groups of healthy laboratory workers, on a group of airmen, on a group of civilians who were attending the Newcastle-upon-Tyne Dental Hospital with acute ulcero-membranous gingivitis, on a group of healthy adults living in the Newcastle-upon-Tyne district, on a group of medical in-patients in the Royal Victoria Infirmary, Newcastle-upon-Tyne, and on four housemen, residents at this hospital. In addition, in all but one of these groups of subjects the test dose of nicotinamide was repeated on five successive mornings, and the amount of nicotinamide methochloride eliminated in the urine for 7 hours thereafter was determined on any of these days which was found to be practicable.

Results

Table I summarizes the results obtained from airmen at Stations I, II, III, and IV. The mean values are lower in those groups with gingivitis than in those with normal gums. The difference is not statistically significant on any one station, but the probability is approximately 50 to 1 against chance selection resulting in the difference between the average for all normal personnel and for all those with gingivitis.

The results obtained during the preliminary tests on groups receiving 200 mg. nicotinamide are given in Table II. No difference was found to exist in the urinary content of nicotinamide methochloride of airmen with non-ulcerative gingivitis, Type B, and those with normal gums, during the two hours after the ingestion of 200 mg. nicotinamide. Civilians suffering from acute ulcero-membranous gingivitis, Type E, however, had lower initial levels, and their response to 200 mg. nicotinamide was less than that of either group of airmen.

TABLE II.—*Mean Nicotinamide Methochloride Urinary Content in µg./hr. among Civilians at Newcastle-upon-Tyne with Type E Gingivitis and among Airmen with Normal or with Type D Gums, before and after the Oral Intake of 200 mg. Nicotinamide*

	Immediately before Nicotinamide	1 Hour after Nicotinamide	2 Hours after Nicotinamide	Nos. Examined
Type E civilians ..	32·3	709	1,203	21
Type B airmen ..	158·6	4,406	7,207	10
Normal airmen ..	158·6	3,248	7,144	10

Table III gives the results obtained from those groups who received 100 mg. nicotinamide. After the first test dose the group of airmen had the highest urinary output of nicotinamide methochloride, the hospital residents were next, and they were followed by the two groups of laboratory workers. There was no significant difference in the responses of Newcastle working-class patients with healthy gums and of those with acute ulcero-membranous gingivitis, both of which were lower than that of the other groups. Neither the airmen nor the hospital in-patients showed any increase in the response after successive doses of nicotinamide, but an increase was found among the laboratory workers, hospital residents, and patients with Type E gingivitis.

Discussion

Since, as stated by Najjar and Holt (1940, 1941a, 1941b, 1942), no fluorescent "F_2" pigment can be obtained from the urine of pellagrins or from that of dogs suffering from

black-tongue, and since the ingestion of nicotinamide, nicotinic acid, or various related compounds results in an increase in the urinary content of "F_2," it is reasonable to suppose that a measure of the urinary elimination of this substance would provide some indication of nutritional status so far as nicotinamide is concerned. Other factors have been found, however, which influence considerably the amounts of "F_2" found in the urine (Ellinger and Coulson, 1944), and in order to lessen their effects early morning specimens of urine were used for the assay during the earlier part of the investigation.

As can be seen from Table I, a difference ($P=0.02$) was found in the urinary "F_2" output of airmen with gingivitis, for the most part Type B, and of those with normal gums. However, the difference is small and the statistical significance is not high. Furthermore, very great daily variations were observed, not only in individuals but also in groups (Table IV shows the results obtained on three successive days at R.A.F. Station IV), and the amount of physical energy expended during the previous day was also observed to affect the urinary excretion, as can be seen from Table V. It is therefore concluded that no aetiological significance can be attached to the slight difference in early morning urinary "F_2" found between airmen with normal gums and those with gingivitis.

So many variables, known and unknown, affected the early morning urine content of nicotinamide methochloride that it was considered necessary to develop a more satisfactory test. It has been found more suitable to estimate the amount of methochloride which is eliminated in the urine during the 7 hours after the ingestion of nicotinamide. Not only are the results obtained consistent on different occasions in individuals with routine habits, but the variation is not great between individuals living under similar conditions. Among 18 airmen living at the same station and eating at the same mess, the mean urinary output of nicotinamide methochloride during the 7 hours after the ingestion by mouth of 100 mg. nicotinamide was 22.8 mg., with a standard deviation of 5.64 mg. and a coefficient of variation of 24.75. The same men were examined on three separate days, and Table VI shows that the individual variation was not great, each man's urinary output of methochloride from day to day tending to remain in the same position relative to the group as a whole. Furthermore, the results obtained from pellagrins give very low values (unpublished data, Ellinger and Benesch); one subject suffering from alcoholic peripheral neuritis whom we have examined eliminated only 3.76 mg., and groups which for social and economic reasons might be expected to be better fed had higher values than groups whose conditions were less satisfactory. It is therefore reasonable to suppose that this test forms a fairly reliable index of nicotinamide nutrition, although other factors do probably influence the results.* No reasons can yet be given for the different reactions of the various groups of subjects to repeated doses of nicotinamide.

TABLE VI.—*Correlation in Urinary Nicotinamide Methochloride Output of 18 Airmen for 7 Hours after receiving 100 mg. Nicotinamide on Three Separate Days*

Group	Means (mg. Nicotinamide Methochloride)		
	Day 1	Day 3	Day 5
A. (The four airmen with lowest outputs on Day 1)	15·9	12·0	14·8*
B. (The five airmen with next lowest outputs on Day 1)	21·0	20·2	21·6
C. (The five airmen with highest outputs on Day 1, excluding those in Group D)	23·7	19·2	19·9
D. (The four airmen with highest outputs on Day 1)	30·3	25·4	32·7
Totals	22·8	19·3	22·4

* Only three airmen of this group examined on this day.
Correlation ratios: Days 1 and 3, + 0·78; Days 2 and 3, + 0·82. (Derived from individual outputs.)

It can be seen from Table III that, within the same groups, there is no significant difference between those with gingivitis Type B or Type E and normal subjects. In view of this, it is concluded that it is unlikely that nicotinamide deficiency played any important part in the development of gingivitis of any type in the subjects who were examined during this investigation. These conclusions are supported by the results obtained after the ingestion of 200 mg. nicotinamide (Table II), but, for reasons stated above, it was found to be impracticable to continue this test.

Summary

The amount of nicotinamide methochloride in the early morning urine of airmen with normal gums was found to be higher than in the urine of those with various types of gingivitis. This difference, although statistically significant, was not considered to be of aetiological importance, since other factors were observed to have a marked influence on the results.

A test has been described which is considered to give a fairly reliable indication of the state of nicotinamide metabolism.

The results obtained with this test were related to standards of feeding. Those getting the best food eliminated the greatest quantities of nicotinamide methochloride after a test dose of 100 mg nicotinamide.

Among subjects who had similar standards of feeding—i.e., who were in the same economic or social class—the response of urinary methochloride to 100 mg. nicotinamide was the same whether gingivitis was present or not.

It is concluded that nicotinamide deficiency probably did not play any part in the development of gingivitis of any type among the subjects examined.

We wish to thank Air Marshal Sir H. E. Whittingham for providing facilities and for his interest and encouragement; Air Cdre. T. McClurkin, Director of Hygiene, for constant and ready help in the organization of the experiments; Wing Cmdr. T. F. Macrae, who inspired much of the work; Dr. B. S. Platt, for taking part in devising the experimental scheme; Dr. Bradford Hill, for help in sampling and for advice concerning the statistical evaluation of the results; Prof. R. V. Bradlaw, for granting exceptional facilities at the Dental Hospital, Newcastle-upon-Tyne; the commanding officers, medical and dental officers of the Royal Air Force stations at which the experiments were carried out; members of the research and technical staff of the Lister Institute, for volunteering as experimental subjects; and Corp. A. E. Wrigglesworth, W.A.A.F., for technical assistance.

THE ERYTHROCYTE SEDIMENTATION RATE IN INFECTIVE HEPATITIS AND IN MALARIA

BY

PAUL WOOD, M.D., F.R.C.P.

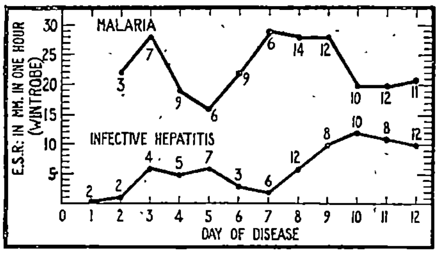
Lieut.-Col., R.A.M.C.

(From a General Hospital in the C.M.F.)

In his lucid and balanced survey of the problems confronting us concerning infective hepatitis Witts (1944) writes: "A major difficulty in the pre-icteric stage is the differentiation from clinical malaria . . . and a simple laboratory test for infective hepatitis would be an immense help." It is the purpose of this short paper to show that in the erythrocyte sedimentation rate we already have such a test at our disposal, subject to its usual limitations, especially as an aid in the differentiation mentioned.

The behaviour of the E.S.R. in 35 unselected cases of infective hepatitis was normal during the first week or ten days, whether there was fever or not. It rose slowly and steadily during the period of biliuria, to reach a maximum commonly between 15 and 30 mm. in one hour (Wintrobe). During the stage of recovery, when the urine was free from bile, the E.S.R. returned slowly to normal, a minority of cases showing further acceleration before this occurred. These conclusions were supported by sporadic readings in other cases, especially the fact that the E.S.R. was normal or low in the febrile or pre-icteric phase, and below 10 during the first week. The accompanying Graph depicts average readings on each day of the disease up to the twelfth day. The numeral above each reading indicates the number of cases from which an average was obtained. This graph does not distinguish febrile from afebrile cases.

The behaviour of the E.S.R. in malaria is in sharp contrast. The Graph shows the average difference during the first 12 days, the malaria graph being constructed in the same way as that just described for infective hepatitis. As no essential difference was observed between M.T. and B.T. cases, nor between fresh attacks and cases of relapse, they have all been shown as one group. The general trend was confirmed by single readings in other cases. The diagnosis rested on a positive blood smear in every instance, and treatment with quinine, gr. 10 t.d.s., was started as soon as it was made. It is not known whether this influences the test; many of the cases had mepacrine also. During the first 10 days the E.S.R. ranged between 12 and 60 mm. in one hour in 28 cases, and was below 10 in only 4; if cases in which only one estimation was made are added, these figures become 43 and 8 respectively. In other words, the E.S.R. during the first 10 days of malaria was over 10 in 84% of 51 cases.



In the infective hepatitis cases, during the first 10 days the E.S.R. was below 10 in 25 instances, and ranged between 10 and 20 in 5; if cases in which only one estimation was made are added, these figures become 30 and 5 respectively. Thus during the first 10 days of infective hepatitis the E.S.R. was under 10 in 86% of 35 cases, and was never higher than 20. In malaria it fell between 20 and 60 mm. in one hour in 23 out of 32 cases, or in about two-thirds of them.

The slow E.S.R. in the early phase of infective hepatitis serves to distinguish it from certain other fevers, but further work is required in this field. The important thing is that in the E.S.R. and in the white count we have two non-specific tests which serve to place a P.U.O. into a certain class or group. It would be helpful if other non-specific group tests could be discovered which would further narrow down the field of differential diagnosis. No attempt was made to investigate the cause of the slow rate in infective hepatitis. It may depend upon the relationship of liver function to fibrinogen and to the serum albumin–globulin ratio.

It was found that the raised E.S.R. in malaria may persist for several weeks. This may be of value in helping to decide whether a case treated as clinical malaria really was malaria or some short-term fever. Of 72 measurements made between the 10th and 20th days in malaria, 60 ranged between 11 and 53 mm. in one hour and 12 were 10 mm. or under—i.e., 84% were raised, often considerably. In a group of 42 cases of short-term fever in North Africa and Italy, without physical signs and with no localizing or upper-respiratory-tract symptoms, the E.S.R. was normal by the end of the first week in 30, and was approaching normal and was under 20 by the end of the second week in the remainder. Some of these cases were probably sandfly fever.

Conclusion

The E.S.R. is shown to be of value in the early diagnosis of infective hepatitis, especially in its differentiation from clinical malaria.

In the first 10 days of infective hepatitis about 85% of cases have an E.S.R. below 10 mm. in one hour (Wintrobe). In the first 10 days of malaria about 85% of cases have an E.S.R. above 10 mm.

An E.S.R. above 20 mm. in one hour during the first week of a P.U.O. practically excludes infective hepatitis; on the other hand, such a reading occurs in about two-thirds of all cases of malaria during the first week.

The E.S.R. serves to distinguish clinical malaria from short-term fevers of uncertain aetiology. In malaria the acceleration is maintained for at least two or three weeks in about 84% of cases; in short-term fevers the E.S.R. is commonly normal within one or two weeks of the onset.

I wish to thank the medical officers in my division for their co-operation in this investigation; the work was theirs, not mine.

TREATMENT OF PLACENTA PRAEVIA, WITH SPECIAL REFERENCE TO THE USE OF WILLETT'S FORCEPS

A REPORT ON 134 CASES

BY

GORDON KING, F.R.C.S., F.R.C.O.G.

Former Professor of Obstetrics and Gynaecology, University of Hong Kong

AND

DAPHNE CHUN, M.B., B.S.

Former Second Assistant, Obstetrical Unit, University of Hong Kong

Methods of Treatment

Broadly speaking, the present-day methods of treatment of placenta praevia may be summarized under two main headings:

1. *Methods which Aim at the Control of Haemorrhage by Producing Pressure on the Bleeding Area.*—An essential feature of these methods is the maintenance of the pressure until full dilatation of the cervix allows of delivery of the child *per vias naturales.* The various methods of producing pressure on the placental site include:

(*a*) *Version.*—In England probably more cases have been treated in the past by "early version and slow extraction" than by any other means. Version (external, bipolar, or internal, in order of preference) is performed, one leg is brought down, and bleeding ceases under the pressure exerted by the half-breech on the placental area. Results in large series of cases show an average maternal mortality of about 7% and a foetal mortality in excess of 70%.

(*b*) *Bag.*—Another method of producing pressure—not very popular in England—is by the insertion of a de Ribes bag or metreurynter through the ruptured membranes. Mild traction on the filled bag produces compression of the placenta against the wall of the lower uterine segment. Reports in the literature show a similar maternal mortality to that seen in version, but a somewhat lower foetal mortality.

(c) *Willett's Forceps.*—In 1925 Willett introduced a simple and effective method of producing pressure on the placenta by fixing a toothed forceps to the scalp of the child and exerting slight continuous traction on the head. The chief advantage claimed for this method is that the foetal mortality is brought down to about 50% or even lower, and that the maternal death rate is reduced to about 3.5%.

(d) *Rupture of the Membranes.*—In a fair proportion of less serious cases rupture of the membranes alone allows of the descent of the head on to the dilating cervix, and the pressure produced by uterine action is sufficient in itself to stop the haemorrhage. In cases in which this simple treatment suffices the maternal mortality drops to about 2%, and a foetal mortality in the region of 30% is found.

2. *Caesarean Section.*—This method represents a much more radical approach to the problem, and was first used in England for the treatment of placenta praevia by Lawson Tait in 1898. After the abdominal delivery of the child, preferably by the lower-segment operation, removal of the placenta is carried out under direct vision and the haemorrhage automatically ceases. This is undoubtedly the method of choice in patients with central and marginal placenta praevia whose general condition is relatively good and in whom sepsis is not a complicating factor. Large series of cases show maternal mortalities varying from 0 to 6.4% and foetal mortalities ranging between 10.5 and 24.5%.

In exsanguinated patients blood transfusion plays a part of the greatest importance, both during and after labour, and has saved many lives in borderline cases. Vaginal packing, formerly employed so frequently, has now fallen virtually into disuse, and is resorted to only on rare occasions when the violence of the haemorrhage makes it essential to use it as a temporary measure.

In Hong Kong, during the period 1936 to 1941, 134 cases of placenta praevia were treated by the university obstetrical unit, with only one maternal death (0.75%) and a combined stillbirth and neonatal death rate of 54.0%. This represents a placenta praevia incidence of 1 in 128, or 0.78% of the 17,099 cases delivered during that period. The main forms of treatment employed were, in order of frequency, Willett's forceps, rupture of the membranes, version, and Caesarean section. An analysis of these cases presents certain features of interest in relation to the indications for the various forms of treatment (see Table I).

TABLE I.—*Treatment Used in 134 Cases of Placenta Praevia of All Types*

Method of Treatment	No. of Cases	Result to Mother		Result to Child		
		Living	Dead	Living	S.B.	N.D.
Willett's forceps ..	46	45 (97·8%)	1 (2·2%)	20 (44%)	16 (34%)	10 (22%)
Rupture of membranes	42	42 (100%)	—	27 (63%)	8 (18·5%)	8* (18·5%)
Version	28	28 (100%)	—	2 (7%)	23 (82%)	3 (34%)
Caesarean section ..	18	18 (100%)	—	13 (72%)	1 (5·5%)	4 (22·5%)
Totals	134	133 (99·25%)	1 (0·75%)	62 (46%)	48 (35·5%)	25* (18·5%)

S.B. = Stillbirth. N.D. = Neonatal death.
* Figures include premature twins.

The type of treatment used was found to depend very largely on four factors: (*a*) the variety of placenta praevia; (*b*) the condition of the cervix on admission; (*c*) the amount of bleeding already sustained by the patient; (*d*) the presence or absence of sepsis. Other factors, such as the parity of the patient, the duration of the pregnancy, the presentation of the foetus, and the existence of additional obstetrical complications, were naturally of importance also in deciding upon the treatment to be employed in individual cases.

The relation between the variety of the placenta praevia and the treatment used is shown in Tables II, III, and IV, dealing with the results in central, marginal, and lateral placenta praevia respectively. It will be noted that 16% of the 134 cases were central placenta praevia, and that there were 40% of the marginal and 44% of the lateral varieties respectively. Broadly speaking, the tables show that Caesarean section was the treatment favoured in central placenta praevia; that Willett's forceps were used most frequently in marginal cases; and that more conservative measures, such as rupture of the membranes, had the most prominent place in dealing with cases of lateral placenta praevia.

TABLE II.—*Treatment of 21 Cases of Central Placenta Praevia*

Method of Treatment	No. of Cases	Result to Mother		Result to Child		
		Living	Dead	Living	S.B.	N.D.
Caesarean section ..	15	15	—	12	—	3

Totals	59	59	—	32	19	9*

* Figures include premature twins.

The method of treatment employed was also influenced to a very large extent by the state of the cervix on admission. Under the conditions prevailing in Hong Kong patients tended to delay coming to the hospital until repeated haemorrhages had taken place, by which time outside examinations had frequently been done and active labour was very often in progress. In the present series of cases it was found that only 22% of the patients were not in labour at the time of admission. Of the remainder, 36% showed varying degrees of cervical dilatation up to 5 cm. (half dilatation), and the other 42% had a cervix which was from half to fully dilated. As many as 22% showed a fully dilated cervix on admission. These facts explain the relatively low incidence of Caesarean section in the series, the operation often being contraindicated in an exsanguinated patient actively in labour and already potentially infected. Caesarean section was chiefly reserved for cases of central placenta praevia with little or no dilatation of the cervix, and in no case was the operation performed when the cervix was more than half dilated. Willett's forceps were most frequently applied when the cervix was 4 cm. (two fingers) dilated, which was the case in about one-half of the applications. In 25% the diameter of the cervix was less than 4 cm. and in the remaining 25% it was greater than 4 cm. at the time the treatment was applied. Version was relatively seldom used on account of the satisfactory results obtained with Willett's forceps, but in the majority of the cases in which it was employed it was reserved for patients in whom the cervix was more than half dilated. In a large number of those with an advanced degree of cervical dilatation simple rupture of the membranes sufficed to control the haemorrhage, particularly in cases of lateral placenta praevia.

The measured or estimated amount of blood loss in this series of cases averaged 912 c.cm. in central placenta praevia. 623 c.cm. in the marginal cases, and 490 c.cm. in the lateral variety. Losses ranged in individual instances from 120 c.cm. to 2,200 c.cm. Blood transfusion was indicated and carried out in numerous cases, but in spite of the routine performance of blood grouping it was not always possible to obtain donors, and massive infusions of saline and glucose had to be substituted on many occasions. Actually, however, no death from haemorrhage occurred in this series.

The presence of sepsis, whether real or potential, was not infrequently of decisive importance in regard to the treatment employed. In this group of 134 cases only 16 had received any antenatal care, thus giving a proportion of 12% booked cases to 88% emergency cases. In many instances outside examinations had been done by unskilled persons, and potential, if not actual, infection was therefore present. Under these circumstances Caesarean section was ruled out in a large number of patients who would otherwise have been suitable candidates for the operation. Version carried with it the risks of intra-uterine manipulation. Use of Willett's forceps came to be regarded as the least risky measure for the patient, if simple rupture of the membranes failed to control the bleeding. The single death in the series was due to sepsis in an emergency case of central placenta praevia complicated by a Bartholin's abscess.

Results

The results of the various methods of treatment are shown in the above tables.

Caesarean section is undoubtedly attended by the best results for both mother and child, and is the treatment of choice in cases of central placenta praevia and severe cases of marginal placenta praevia. In the 18 cases of this series there was no maternal death and only one stillbirth, but there were 4 neonatal deaths—an unduly high figure which was mainly due to prematurity and malnutrition. For the reasons detailed above Caesarean section was not performed more often. Caesarean hysterectomy was done in one case (a 7-para aged 37) on account of persistent haemorrhage from an atonic uterus after removal of the placenta.

Rupture of the membranes, with or without other conservative measures, such as the application of an abdominal binder and the occasional use of low forceps, gave the next best results. The 42 cases in which this treatment was used were, however, the less severe ones, as evidenced by the fact that the average blood loss was only 480 c.cm. in this group. In many cases in which it had been intended to apply Willett's forceps it was found that the simple rupture of the membranes sufficed to control the haemorrhage and that further treatment was unnecessary. No maternal mortality occurred in these cases, and there was a 63% survival rate of the infant.

Version.—This method was used in 28 cases, and, although attended by no maternal deaths, it showed the customary unfavourable result for the child. There were 23 stillbirths, 3 neonatal deaths, and only 2 surviving children. The average amount of blood lost by the mother during labour was 545 c.cm.

Willett's Forceps.—This method of treatment was employed in 46 of the patients. There was one maternal death in a bad case of central placenta praevia with a discharging Bartholin's abscess containing positive cultures of gonococcus, *Staph. albus*, and *Str. faecalis*. Caesarean section was contraindicated, and as a last resort Willett's forceps were applied. Delivery was effected with a blood loss of only 600 c.cm., but the patient succumbed to sepsis on the seventh day of the puerperium. With this single exception all the mothers survived. The average maternal blood loss was 650 c.cm., and the haemorrhage usually ceased dramatically on the proper application of Willett's forceps with light traction. Of the babies, there was a survival rate of 44%, and there were 34% stillbirths and 22% neonatal deaths. Prematurity and asphyxia accounted for nearly all the cases of infant death. It must be borne in mind, also, that the nutritional standard of the mothers was generally very low and that many of them were suffering from beriberi—a factor which undoubtedly had an influence on the foetal death rate. In the great majority of cases the punctured scalp wound healed rapidly with no complications, and was often difficult to detect on the day after delivery. In a few cases a cephalhaematoma developed beneath the site of application of the forceps. In one case a baby of 38 weeks' maturity, weighing 4½ lb., developed infection of the scalp and died on the eighth day.

Discussion

While it is granted that, under ideal conditions, the most favourable results in the treatment of placenta praevia are to be obtained by the judicious use of Caesarean section, the obstetrician must be prepared to treat cases under less favourable conditions, where the operation is contraindicated. The above series of cases is of interest in that it represents a group in which less favourable conditions prevailed. Caesarean section was frequently ruled out on account of the presence of sepsis and other complications, and was therefore used in only 14% of the series. In the treatment of cases in which delivery by the vaginal route must be undertaken, it is our opinion that Willett's forceps should occupy a leading place.

In 1925 J. A. Willett first described the forceps that have been called by his name, and they have been used more or less extensively since that date. Modifications of the instrument have been introduced by Gauss (1934) and DeLee (1939). Of recent years, however, there has been a tendency to decry the use of the forceps. Bourne and Williams (1939) stated that "Willett's forceps have fallen somewhat into disuse, but are still of value in the treatment of lateral or marginal cases in which artificial rupture of the membranes and the application of a binder have proved insufficient to control haemorrhage." F. J. Browne (1939), after an experience of two cases in which the use of the forceps was followed by *B. welchii* infection of mother and foetus, has gone so far as to conclude that Willett's forceps should have no place in the treatment of placenta praevia, in spite of the fact that the maternal mortality of 252 reported cases was only 3.5% and the foetal death rate 46.4%.

The *disadvantages* of Willett's method are: (*a*) It is only applicable to vertex presentations. (*b*) The forceps may pull off, but this seldom happens if an adequate fold of foetal scalp is secured and a traction weight not exceeding 1 lb. is used. (*c*) It may fail to stop the bleeding, but this is rarely seen after an efficient application of the forceps. (*d*) Maternal infection may occur, as in the cases reported by Browne. (*e*) Wounding and infection of the foetal scalp may be seen, and are more likely to occur if there has been more than one application of the forceps or if the instrument has been allowed to tear off.

On the other hand, the *advantages* claimed for the method are: (*a*) The use of the foetal skull as an instrument for compressing the placental site compares very favourably with that of the breech, a bag, or gauze packing, on account of the smooth and accurate manner in which it fits the lower uterine segment. (*b*) The method can be used when the os will admit only one or two fingers, at a time when it may be difficult or impossible to bring down a leg. (*c*) Efficient application of the forceps and the exertion of mild traction, never exceeding 1 or 1½ lb., are nearly always followed by abrupt cessation of the haemorrhage. (*d*) Very little internal manipulation is required to make the application, as compared with that necessary to perform version or to insert a bag, thus minimizing the risk of introducing sepsis or of aggravating infection which may already exist. (*e*) The foetal mortality is relatively low: it may be stated in round figures that with Willett's forceps the survival rate for the child is in the region of 50%, whereas with version the mortality rate is in excess of 70%.

The value of the method is therefore very clear, and it would appear that its advantages distinctly outweigh its disadvantages when compared with version, which is its chief rival in the therapeutic field. In remote districts where facilities for Caesarean section are not available, or where the practitioner is confronted with a case requiring immediate treatment, the use of Willett's forceps has often proved to be a simple, efficient, and life-saving measure. We have come to the conclusion that the use of Willett's forceps should take pride of place in the treatment of placenta praevia in cases in which Caesarean section is contraindicated and in which simple rupture of the membranes and the application of an abdominal binder fail to control the haemorrhage.

Summary

A series of 134 cases of placenta praevia is reported, of which 16% were central, 40% marginal, and 44% lateral in their situation.

There was one maternal death (0.75%) in the series, and the combined stillbirth and neonatal death rate for all methods of treatment was 54.0%.

The child mortality rate accompanying the different methods of treatment was as follows: Caesarean section 28%, rupture of membranes 37%, Willett's forceps 56%, version 93%. An unusually high neonatal death rate was encountered in this series, due to the frequent combination of prematurity with malnutrition and B_1 avitaminosis in the newborn.

The use of Willett's forceps in the treatment of placenta praevia is advocated in cases in which Caesarean section is contraindicated and in which artificial rupture of the membranes fails to control the haemorrhage.

We desire to make due acknowledgment to the former Director of Medical Services, Hong Kong, through whose courtesy clinical facilities were made available for the treatment of these patients.

NYLON FOR BURIED SUTURES

BY

HERBERT HAXTON, Ch.M., B.Sc., F.R.C.S.
Department of Surgery, Radcliffe Infirmary, Oxford

"All real surgeons have been interested in wound repair" (Whipple, 1940). The nature of the material used for suturing wounds has an important influence on their healing, and it behoves all whose work involves the inflicting and the repair of wounds to give much thought to the subject of suture materials.

Catgut

Catgut is easily the most popular substance for buried sutures. Most surgeons get what appear to be reasonably good results with it, and the property of absorbability is one which has a popular appeal. Nevertheless, its disadvantages are not few, and they have been repeatedly pointed out in surgical literature. Inherently infected with spore-bearing organisms as catgut is, its sterilization has always been a difficult problem. The serious infections which all too often followed its use caused Kocher, quoted by Halsted (1913), to exclaim, "Away with the catgut," and persuaded him to use silk instead. In recent years the sterilization of catgut has become effective on the whole; it is stringently supervised, and rightly so. Nevertheless there is always a possibility of a dangerous infection arising from its use.

The fact that catgut is an animal material capable of absorption in the tissues of the body is in some respects a disadvantage. Catgut can produce an allergy, when its subsequent use results in a marked local reaction, rapid absorption, and disruption of the wound (Kraissl, Kesten, and Cimiotti, 1938). Furthermore, it can be absorbed only by provoking an inflammatory reaction, with leucocytic infiltration and exudation of serous fluid, accompanying the resolution of which is an extensive fibrosis. This reaction often causes a serous discharge from the wound which delays healing. Babcock (1935) reported oedematous wound-edges which separated and remained moist for several weeks following the use of subcuticular catgut sutures in thyroidectomy. This did not occur when silk was used. Dunphy and Botsford (1939) and Puestow (1940) reported identical findings. Jenkins and Dunham (1943) attributed part of the inflammatory reaction to the irritant hydrocarbons with which the catgut is treated during its preparation. That wounds sutured with catgut gain tensile strength more slowly than those repaired with silk was shown by the experiments of Howes (1933) and of Localio, Casale, and Hinton (1943). Confirmation is found in Whipple and Elliott's (1938) findings that the incidence of wound disruption was more than eight times greater after catgut had been used than after silk. Jenkins (1937) noted a marked degree of catgut digestion, and Fallis (1937) an inflammatory reaction with serous exudation in disrupted wounds after catgut suture. Parsons (1937) had a recurrence rate of 12.7% for hernias repaired with catgut and only 3.5% with silk, using the same technique.

In his famous paper on surgical technique Halsted (1913) remarked: "It should be borne in mind that during the greater part of the period of its disintegration the catgut suture is not only serving its purpose but is playing the role of necrotic tissue, of a culture medium." This dead animal tissue is indeed a favourable soil for bacterial growth, maintained as it is at body temperature in wounds, and it is not surprising to find that observers have noted that wounds in which catgut has been buried are peculiarly prone to infection. Meleney (1935), in a large series of clean cases, found that the incidence of infection in wounds sutured with catgut was three times as great as in those sutured with silk. Whipple (1940) extended the same series to several thousand cases, for which the figure was 2.5. In Shambaugh's (1937) series of hernias catgut repairs were infected twice as often as silk, while the incidence of minor complications, such as serous discharge, was eight times as great in the former as in the latter. Elkin (1940) found the incidence of infection after catgut to be 4.5 times as great as after silk. Meleney (1935) reported Vivier's findings that, of experimental wounds sutured aseptically with fine silk and catgut, the latter contained more bacteria throughout the healing period. Shambaugh and Dunphy (1937) found that experimental wounds sutured with silk tolerated bacterial contamination better than those in which catgut was used, and Cutler and Dunphy (1941) concluded that the degree of infection in infected wounds sutured with silk was, on the whole, less than in those repaired with catgut.

It is obvious, from this mass of evidence, that catgut is by no means the ideal suture material.

Silk, Linen, and Cotton

In the field of non-absorbable materials silk, cotton, and linen threads have been used with success in clean wounds. Halsted (1913) stated that the results with silk, properly used, were so perfect that he thought its use would become general. It has been the experience of many, however, that infection in a wound sutured with these materials often results in a discharging sinus which will not heal until the sutures and ligatures have been expelled—a process which may take several months. The reason for this severe drawback to their use probably lies in the fact that the threads are made up of many filaments, among which bacteria may multiply beyond the reach of the body's defences.

Nylon

Nylon is a new-comer to the field of filaments. Being a synthetic product it is sterile when manufactured, and it cannot harbour organisms in its interior. It is in common use as a substitute for silkworm-gut in skin sutures, but it has been little employed as a buried material. Nylon is obtainable as a solid, or monofilament, thread and as a woven or twisted multifilament thread. Nichols and Diack (1940) tested the latter in experimental wounds and found that it produced about the same cellular reaction as silk, both being much less irritant than catgut. Aries (1941) found that monofilament nylon produced still less reaction, and that when wounds were infected the inflammation and leucocytic reaction subsided more rapidly round nylon than round silk. Melick (1942) confirmed experimentally the minimal foreign-body reaction of nylon, and he used the multifilament material for the repair of 25 inguinal hernias with satisfactory results. Stonham (1942) used nylon for buried sutures in some operations, and concluded that it was superior to silk and silkworm-gut in clean wounds. Localio, Casale, and Hinton (1943) found that the tensile strength in wounds increased more rapidly when nylon was the suture material than when silk, cotton, catgut, or steel wire was used.

In a series of experimental wounds in the abdominal walls of rats, sutured with nylon and with catgut and examined from 2 days to 8 weeks after operation, I found that those sutured with catgut were always the more inflamed and more oedematous, were adherent to the overlying skin, and in 10% of them pus was present round the catgut. The wounds sutured with nylon healed smoothly and rapidly, with a minimum of inflammation and fibrosis.

In 300 operations I have used nylon for all buried sutures and ligatures, as well as for skin sutures, and have never had cause to regret it. The range of operations was very comprehensive, and the extremes of age were 12 hours (repair of exomphalos) and 91 years (cholecyst-gastrostomy). Even in the presence of infection (for example, 76 appendicectomies, in many of which free pus was present) there was no tendency for the sutures or ligatures to be extruded. Colostomies, too, have been closed without trouble. Wounds healed rapidly and soundly, and with a noteworthy freedom from complications. Sutures have been removed on the sixth post-operative day, as a rule, in abdominal cases, and it has been my experience that it is not safe to remove them so early when catgut has been buried in the wound, particularly if the superficial fascia has been sutured with it. On several occasions, when a second operation was necessary, the previous nylon sutures were found to have a minimum of surrounding fibrosis. The cases have been followed up for periods of from 1 to 9 months and no symptoms referable to the buried nylon have been elicited.

Technique

Several points of technique should be mentioned. Sterility is achieved by immersion in boiling water for 30 minutes. For nearly all purposes the fine (No. 3) monofilament nylon, prepared in 40-inch lengths, is used, the strong (No. 5) being reserved for the ligation of large vessels and where there is tension. Suturing is facilitated by tying the nylon to the eye of the needle with a half-knot. At first Halsted's principle of universal interrupted sutures was adhered to, but it was soon found that continuous sutures could be used with impunity.

It has been said that monofilament nylon is difficult to use because of its springy nature, its smooth surface which makes knots tend to slip, and the small diameter which makes it difficult to feel between the fingers. The technique of using it is easily acquired, however, and it soon becomes very pleasant material to handle. The smoothness with which it glides through the tissues is quite a revelation after catgut or silk. The so-called "nylon knot" is tedious to tie, and it slips easily; the one which I employ is made by tying two half-knots with one end—the long one—held taut (Fig. 1). The ligature is run up tight, and is locked by a third half-knot tied with the short end held taut (Fig. 2). This knot does not slip, and I have used it in the ligation of large vessels, including the femoral artery. Long ends should not be left, and assistants are trained to cut them close to the knot. Tension sutures are not employed, for I am not convinced that they contribute materially to the strength of the wound, and they produce unsightly scars across it and delay healing.

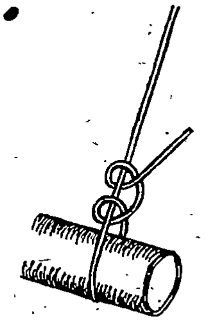

FIG. 1

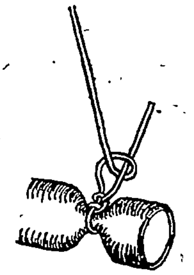

FIG. 2

It is not suggested that there is no place for catgut. I still employ it for the mucosal sutures in most bladder and stomach operations, because non-absorbable sutures may cause trouble in these sites. Nevertheless, for nearly all sutures and ligatures nylon has definitely established its superiority in my cases. An additional consideration is the fact that the cost of nylon for surgical work is only one-eighth that of catgut.

Summary

The presence of catgut in a wound leads to increased inflammation and induration, greater exudation of serum, delay in healing, and an increased incidence of wound infection and breakdown.

Silk, linen, and cotton threads are free from these disadvantages, but may cause great delay in healing if infection is present.

Nylon causes a minimum of tissue irritation, and its use as a buried suture material in 300 operations has shown its superiority to the materials in common use. Wounds healed rapidly and with no complications.

I wish to express my thanks to Prof. Burn, of the Pharmacology Laboratory, Oxford, for providing the facilities for the animal experiments.

Medical Memoranda

Parotitis due to Unusual Foreign Body in Parotid Duct

References in the literature to foreign bodies in the salivary ducts are few. Mittermaier (1929) mentions "bristles, fish-bones, hair, grain and seeds, splinters of wood, etc."; Illingworth and Dick (1941) state that "on rare occasions a foreign body, such as a piece of straw, a fruit seed, or mycelia of actinomyces, may form a nucleus for stone formation"; and Tramer (1938) reported a case in detail. The following account may therefore be worth recording.

CASE HISTORY

The patient was a girl aged 6 years who complained one evening of pain in the right side of the neck, which within a few hours had become swollen below the ear. On examination next day the right parotid gland was moderately enlarged and tender, and thin purulent fluid was seen escaping from the orifice of the right parotid duct. The mouth and throat were otherwise normal, and nothing could be felt on palpation of the duct; the temperature and pulse were 100.5° F. and 120 a minute respectively.

The following day the temperature was 98.4° F. and the pulse 100, but the local swelling and tenderness were more marked. After cleansing the mucosa round the duct orifice with spirit before taking a swab of the pus, slight pressure was made on the duct. Purulent fluid appeared from the opening, and was followed by what seemed to be a bristle, one portion (the last to leave the duct) of which was coated with pus. Chewing-gum was given to help drainage by stimulating the salivary flow, and a course of sulphapyridine was started. The fluid seen flowing from the duct next day was indistinguishable from normal saliva, and as it seemed unnecessary the sulphapyridine was stopped after a total of 6 g. had been given. Two days later the gland was no longer enlarged; the temperature was normal, and, except for slight local tenderness, which disappeared after a further five days, recovery was complete.

Dr. J. B. Penfold examined the pus and the foreign body and reported as follows: "Film: Many pus cells, few epithelial cells, and numerous mixed organisms. Culture: Mixed growth of normal mouth organisms. Foreign body: Husk of seed 6 mm. by 1.5 mm. diameter, with tail 4 mm. long." He submitted the husk to Dr. E. J. Salisbury, Director of the Royal Botanic Gardens, who identified it as "a floret of one of the cultivated forms of the common rye grass, *Lolium perenne*. This form has a fairly long finely barbed awn, which was no doubt responsible for setting up irritation."

Foreign bodies are more common in the submandibular duct on account of its larger size and the position of its orifice on the floor of the mouth (Mittermaier, 1929). Both the site and the nature of the foreign body are unusual in this case. Tramer (1938) describes the case of a child 6 years old who developed parotitis lasting, with fluctuations in its severity, for well over one month: on the forty-first day an incision was made into the parotid, from which pus (giving a mixed growth of organisms) discharged for 31 days. A foreign body was seen in the wound on the thirty-first day and removed; at the end of a further six days the wound was healed completely. The foreign body proved to be a fragment of grass seed, consisting of a husk and a piece of stalk, but was too incomplete for exact identification.

The present case and that of Tramer both occurred in young children, who are more likely than adults to put unusual objects in the mouth. In this case the possible origin of the husk from some cereal food is rendered unlikely by its completely undamaged condition, and as the child lives on a farm she has ample opportunities for eating raw grass seeds.

I wish to thank Dr. J. B. Penfold, pathologist to the E.P.S. Laboratory, Billericay, and Dr. E. J. Salisbury, Director of the Royal Botanic Gardens, Kew, for examining the specimens.

R. H. Trinick, M.B., B.Ch., B.A.O.

A Domestic Case of Chlorine-gas Poisoning

During the past few years much time and much energy have been devoted to the detailed organization of schemes for dealing with the effects of the possible use of gas warfare by the enemy. Fortunately these schemes so far have not been put to the test, and as a result the personal knowledge of many of us on this subject is almost entirely theoretical. It was therefore with no little interest that a clinical case of chlorine-gas poisoning came to our notice recently, and it is rather ironical to reflect that this solitary gas casualty occurred as a result of mixing two common household cleansing agents. The history of the case was as follows.

Case History

At about three o'clock one afternoon Mrs. X., a Birmingham housewife, began to clean her bath. Her husband had recently decorated the bathroom and she was particularly anxious to remove all stains from the bath, and accordingly decided to use both harpic and parozone. She sprinkled harpic liberally into the bath, using about 2 oz., and then poured on about half a pint of parozone. The bath was quite dry at the time and the door of the bathroom was closed. She noticed the sizzling which occurred on mixing the two substances, but did not attach any importance to it, and as she had lost her sense of smell in childhood she remained quite unaware of any possible danger, and continued with her cleansing, leaning well over the bath for the purpose and scrubbing vigorously. Her eyes soon began to water and she felt a pain in her chest on breathing; then she must have fainted, because the next thing she remembers is lying on the bathroom floor. She couldn't stand up, but crawled to the head of the stairs and eventually got down them and out into the garden. Here she was violently sick. Breathing was very difficult and painful; she felt as if she was choking, and was quite certain she was going to die. There was no one else in the house and, finding that her voice was too weak to call for assistance, she threw stones to attract her neighbours, but was unsuccessful in doing so. After a considerable time she managed to crawl upstairs and on to her bed, where she was found by her family on returning from work between 5 and 6 p.m.

One of us (L. M.) saw the patient about 7 p.m. and found her lying on her right side on the bed fully dressed. Her breathing was obviously distressed, the lips were cyanosed, and the pulse was strong and regular and the rate 100. Rales and sibilant rhonchi were present over the front and sides of the chest: a detailed examination was not deemed advisable because of her general condition. Treatment consisted of rest in bed and an expectorant mixture, but on the following day a linctus had to be substituted for the expectorant mixture because of incessant coughing. Her progress was satisfactory, and she was allowed up after three days; but three weeks later she still complained of unusual fatigue.

Comment

It was decided to investigate the effect of mixing parozone and harpic, and accordingly samples of each were bought and submitted to the city analyst, who reported as follows:

> "Parozone is a solution of sodium hypochlorite containing 5.8 w/v of available chlorine. Harpic is impure acid sodium sulphate containing 77% $NaHSO_4$. Harpic, acting as an acid, liberates the chlorine from parozone. If 1 oz. of parozone is mixed with 1/3 oz. of harpic all the available chlorine is liberated and about 1.4 g. (equal to 500 ml.) of the gas would be given off. This amount would be reduced considerably if water were added, the solubility of chlorine in water being about 8 g. per litre. The limit of insupportability—i.e., the highest concentration which a person can breathe for 1 minute—is given as 100 mg. per cubic metre, so that a mixture of 1 oz. of parozone and 1/3 oz. of harpic would produce 14 cubic metres (equal to 450 cubic feet) of insupportable air. An average bath would have a capacity of approximately 50 cubic feet."

The 2 oz. of harpic used by Mrs. X. would be enough to liberate all the available chlorine from 6 oz. out of the 10 oz. of parozone used, so that about 3,000 c.cm. of chlorine gas must have been given off, and as the bath was quite dry all the gas would remain in the atmosphere. Being a relatively heavy gas, the highest concentration would be expected in the bath itself, and as Mrs. X. leant well over the bath, and was presumably breathing fairly heavily from her exertions, there can be little doubt that she must have inhaled an appreciable quantity of chlorine gas. It is likely that anyone with a normal sense of smell would have withdrawn from the atmosphere very much sooner than the patient did, and for this reason no general conclusions should be drawn from this isolated case.

A Case of Accidental Intestinal Myiasis

The following case seems to be interesting enough to be placed on record.

Case Report

A previously perfectly healthy man of 22 was carried into sick quarters at 10 o'clock one morning, having suddenly collapsed. He had felt quite well when he got up at 7 o'clock, was very hungry, and ate a good breakfast. Approximately 1½ hours afterwards he suddenly "broke out" in a cold sweat, nearly fainted, and then had a violent urge to defaecate. This proved impossible. He had no tenesmus. This desire to defaecate was immediately followed by nausea, severe vomiting, and vertigo. At no time did he have abdominal pain.

On examination the face was pale, the skin cold and clammy. The pulse rate was 64, weak but regular, and respirations were 16 a minute. The temperature was normal. The tongue had a heavy white coat, the pharynx was normal, the breath was not foul. The eyes were normal, the pupils being equal and reacting normally to light and accommodation. The abdomen and all other systems showed no abnormality on careful examination. The patient had vomited violently before arrival at sick quarters, and consequently the vomit was not available for examination, which later proved rather unfortunate.

He was admitted and put straight to bed, with hot bottles. No food was permitted, and an excessive fluid intake was encouraged. He was retching continuously, but did not vomit again. The retching was successfully treated with a few drops of tincture of iodine in water. During the afternoon his bowels moved once, but beyond being rather loose showed no other obvious abnormality. The next morning all nausea had vanished. He passed a very loose motion which was full of blood and mucus. This specimen was sent to the laboratory, and the following report was received: "Pus, blood, mucus, and macrophages present. Faecal debris, *nil*. No ova or parasites seen. Culture: No pathogens isolated." An ounce of castor oil was given and the starvation diet continued, the patient being allowed only fluids. In the evening he developed a temperature of 101° F. and a severe frontal headache; the next morning, however, the headache had gone and the temperature was normal. The patient himself was looking and declared that he felt much better, though still rather weak. He had a strong desire to eat. No physical signs were found in the abdomen. The motion was still very loose, and contained a large proportion of blood and mucus. It was also found to contain large numbers of live, highly active larvae. These were at once isolated, sent to the laboratory for identification, and proved to be the larvae of *Stomoxys calcitrans* (the stable fly), a fly reported to be capable of producing intestinal myiasis. He was given a further ounce of castor oil, and during that day his bowels opened five times. Each motion contained macroscopic blood and mucus, but no more larvae were passed. On the morning of the third day of the illness the patient was feeling considerably better, and had by then developed a ravenous appetite. The diarrhoea had cleared, but the two specimens he passed that day both contained more larvae, though these were no longer active. A further specimen was examined at the laboratory, and the report received was: "A few pus cells and undigested vegetable cells. Larvae still present."

On the fourth day only one motion was passed. This was normal, and no further evidence of larvae was found. On the morning of the fifth day another normal motion was passed, and the patient appeared to have recovered completely. No larvae could be found. The patient was allowed to eat, and in the evening he was permitted to get up. The next day he was given a full diet and allowed to walk around the ward all day. All symptoms had cleared, bowel motions were normal, and no further evidence of larvae appeared. He was finally discharged on the morning of the seventh day of the illness apparently completely recovered, and no relapse of symptoms had been reported up to the time of writing this report, 14 days after discharge from sick quarters.

On finding the larvae, coupled with the fact that the patient had a strong desire for food—an unusual finding in a patient suffering from acute bacillary dysentery—supported also by the fact that culture of the faeces had produced no pathogenic growth of organisms, a diagnosis of intestinal myiasis was made. In view of the species of larvae discovered it was felt that this case was almost certainly "accidental." On questioning the patient he stated that a few days previously he had eaten a large number of cherries and plums, which he had not washed, and that he had placed them whole in his mouth without first examining them or removing the stones. It is believed that this constituted the source of infection. The fruit must have been harbouring the larvae round the stones, and the patient had eaten them, subsequently developing the acute attack described.

Reviews

A BOOK ON MEDICAL DIAGNOSIS

Medical Diagnosis. Applied Physical Diagnosis. Edited by Roscoe E. Pullen, A.B., M.D. (Pp. 1,106; illustrated. 60s.) Philadelphia and London: W. B. Saunders Company. 1944

This textbook of medical diagnosis aims at greater comprehensiveness than the ordinary students' manual. Regions like the skin, the breasts, and the extremities are dealt with at some length, and there are separate sections on the endocrine and the reproductive systems, and on the sterility survey. Psychological and psychiatric diagnosis are also included, and industrial and military medicine are not forgotten. The book is well produced, and Chapter VIII, on the examination of the breasts, to give only one example, is a brilliant exposition of teaching by text and illustration. Nevertheless this is not a book we can whole-heartedly recommend, and a paragraph from the chapter on examination of the skin will serve as a text for our criticism:

> "*Eggshell* nails, soft, somewhat transparent, easily bent and split may indicate arthritis, peripheral neuritis, leprosy, or hemiplegia. *Beau's lines,* transverse lines or superficial sulci, may occur after acute infectious diseases, syphilis, tuberculosis, or nervous diseases. *Onychomadesis,* or shedding of the nails, has been observed in arsenical poisoning and diabetes. *Hypertrophic* nails may result from neglect or chronic dermatoses. They may indicate an endocrine disease. *Heaped-up detritus* under the free edge of a nail may be due to fungous infection or psoriasis, particularly that type of psoriasis which occurs in association with arthritis. A painful 'paronychia' may actually be a syphilitic chancre. The presence of epitrochlear adenopathy should be noted."

Uncorrelated factual information of this type is quite unsuitable for the undergraduate student. What he needs to learn is the principles of clinical examination, and this string of facts has no more relevance to them than a list of Solomon's concubines to the study of theology. On the other hand, the information is much too incomplete for a book of reference. Koilonychia, or spoon-nails, is not mentioned in the text or the index. The experienced graduate, in fact, would find that the kind of uncommon information he wanted about finger-nails was not given here, and he would have to seek it in one of the standard works on dermatology. Turning to another section, we looked for guidance on the examination of a painful shoulder and failed to find it. It seems to us, in fact, that Dr. Pullen and his collaborators have failed in a task which ought never to have been attempted. That task is the divorcement of physical diagnosis from the other aspects of the study of disease. A good deal of nonsense has been written lately about the alleged lack of powers of observation shown by modern medical students. Most of the writers would be unable to say what was the colour of the eyes of the last person they saw, what side he parted his hair, or whether or not he had a moustache, in spite of the fact that they may be quite good doctors. They have overlooked the fact that medical diagnosis is a quite specialized type of observation, like judging the points of a cow or the weight of a cheese. The duty of medical teachers is to inculcate this specialized type of observation, and yet keep alive in their pupils the generalized and unconventionalized powers of observation which are characteristic of an intelligent small boy. This is not an easy task, and we do not think Dr. Pullen's book will make it any easier.

PRACTICAL ANAESTHETICS

Textbook of Anaesthetics. By R. L. Minnitt, M.D., D.A., and John Gillies, M.B., Ch.B., D.A. Sixth edition. (Pp. 487: illustrated. 25s., plus 9d. postage.) Edinburgh: E. and S. Livingstone.

This well-known textbook, originally written by Ross and Fairlie, now has the name of J. Gillies added to the title-page. The subject-matter has obviously undergone an extensive revision, and new chapters on trilene, endotracheal, intravenous, and dental anaesthesia added. Full descriptions of practical matters will make this book appeal particularly to the beginner in what is, after all, a very practical specialty. The general standard of the book is so good that it is difficult to choose any one section for special commendation. The chapter on the choice of the anaesthetic serves as an example; it gives a liberality of sound advice for which mature experience has been responsible, and which can be followed with confidence. Some of the theoretical matter in the book is open to question. For example, the opinion that anaesthesia without rebreathing causes acapnia and may be harmful will not find general acceptance. Fig. 46 is marred by a failure to account for liquid nitrous oxide in a cylinder the pressure in which has already fallen considerably.

A short section on local analgesia is also included. This is not up to the general high standard of the book in so far as its usefulness to the novice is concerned. While serving as a brief account for pre-examination revision, the descriptions are too short and the illustrations too scanty to be of use to one who intends producing regional anaesthesia for the first time. Only 5½ lines are given to heavy nupercaine spinal analgesia, while the spinal techniques of Sebrechts and Lake receive a paragraph each, and 10 pages are devoted to local analgesia for dentistry.

The book is beautifully produced by E. and S. Livingstone, Ltd., and is undoubtedly an important modern textbook on anaesthetics.

THE FAMILY SITUATION

Family Situations. An Introduction to the Study of Child Behavior. By James H. S. Bossard and Eleanor S. Boll. (Pp. 265. 18s. 6d.) Philadelphia: University of Pennsylvania Press; London: Oxford University Press.

In the study of behaviour we must consider the individual and the environment, and the elements of the environment are termed "situations." For the child the most important situation is the family situation, which is the subject of this book. The study of situations is the province of sociology, and the object of the book is to show how the study may be systematized and made more scientific. Situations may be regarded from three points of view—structure, process, and content. Social situations are not constructed as are those of the physiologist and often of the psychologist, but are found as they are and merit careful independent study. Family situations can be so studied and classified in the three groups mentioned. The second part of the book consists of examples culled not from original observation but from literature and "the literature." These are dealt with under the headings: (1) Intrafamily relationships, which include the divided home, the new-arrival home, the mother-controlled home, and so on, with their effects on the child's security; (2) family patterns, such as the nomadic family, the social-climber family, the over-religious family, and so on; and (3) external factors, such as the farm family, the city family, and the home of the invalid. Finally there is a chapter on how the sociologist should approach this study, which is obviously an important one.

This is an interesting book. It will give all those who are concerned with the study of how the individual reacts to his environment (and what doctor should not be?) much food for thought.

ORTHOPTICS

The Practice of Orthoptics. By G. H. Giles, F.B.O.A., F.S.M.C. Foreword by Air Vice-Marshal Sir David Munro. (Pp. 366; illustrated. 25s.) London: Hammond and Hammond.

An authoritative exposition of the possibilities and limitations of orthoptic treatment in squint is as yet to come. It is not a slur on Mr. G. H. Giles that his book hardly satisfies these exacting criteria; the subject is still too fluid and the present book reflects the uncertainties of this field of study only too well. The author would, however, have done better to have confined himself strictly to the field he has attempted to survey rather than include a mass of more or less irrelevant detail on refraction. The whole structure of the book reflects the limited outlook of the non-medically trained optician. Refraction work is dealt with here as part of the particular anomaly of squint, instead of being regarded as a standard method of investigation. Again, the stress on the psychological factor, while undoubtedly valid in viewing the problem as a whole, somehow ends in this treatise with a quasi-judicial assessment of "naturopathic" methods. None the less there is here a mass of useful information drawn from the scattered literature, but patience as well as interest is needed to read its exposition.

Notes on Books

A Bibliography of Aviation Medicine Supplement, by P. M. HOFF, E. C. HOFF, and J. F. FULTON, is distributed for the Committee of Aviation Medicine, National Research Council of America, by C. C. Thomas, 327, East Lawrence Avenue, Springfield, Ill., at $2.50 post paid. The previous *Bibliography of Aviation Medicine* gave a very complete list of references upon all subjects which relate to aviation medicine, up to about the time of America's entrance into the war. The present *Supplement* brings the earlier list up to date. It is of course only up to date so far as it includes all papers which have been published, but it is everyone's misfortune that most of the more important papers will have to remain unpublished until hostilities have ceased. With this single serious qualification the *Supplement*, which is most admirably compiled and set up, can be heartily recommended.

The Lady of the Hare: A Study in the Healing Power of Dreams, by JOHN LAYARD, D.Sc. (Faber and Faber; 12s. 6d.), is a study of Jungian psychology by a non-medical psychologist who had undertaken the treatment of a countrywoman with a mentally deficient daughter and a neurotic sister (so is the diagnosis). Twelve interviews at roughly weekly intervals were all that were needed to cure the patient of rheumatism and dyspepsia, to improve the intelligence of the daughter and the temper of the sister and the relationship of all three. The dreams of the patient are recorded, and especial attention is drawn to one in which she sacrifices a hare. This is made the central theme of the narrative of how the purifying and revealing forces of the unconscious well up and influence not only the individual but those in contact with her. The hare was the symbol of redemption for this patient, and the author later discovered that the hare figured in folklore in a similar connotation all over the world. This folklore is described in the second part of the book and certain aspects of Jungian philosophy are discussed, especially the interplay of animus and anima (the father and mother, masculine and feminine symbols) and the complementary nature of conscious and unconscious. The author also relates the struggle between the instinctive and spiritual qualities with the resurgence of religion. This book will interest those brought up in the school of Jung and others concerned with mythology and psychological theories, but many plain medical practitioners will find it hard to understand or to be convinced by it.

Preparations and Appliances

AN ANAESTHETIC FACEPIECE FOR USE IN THORACIC SURGERY

Dr. H. J. V. MORTON, senior anaesthetist, Hillingdon County Hospital, Uxbridge, Middlesex, writes:

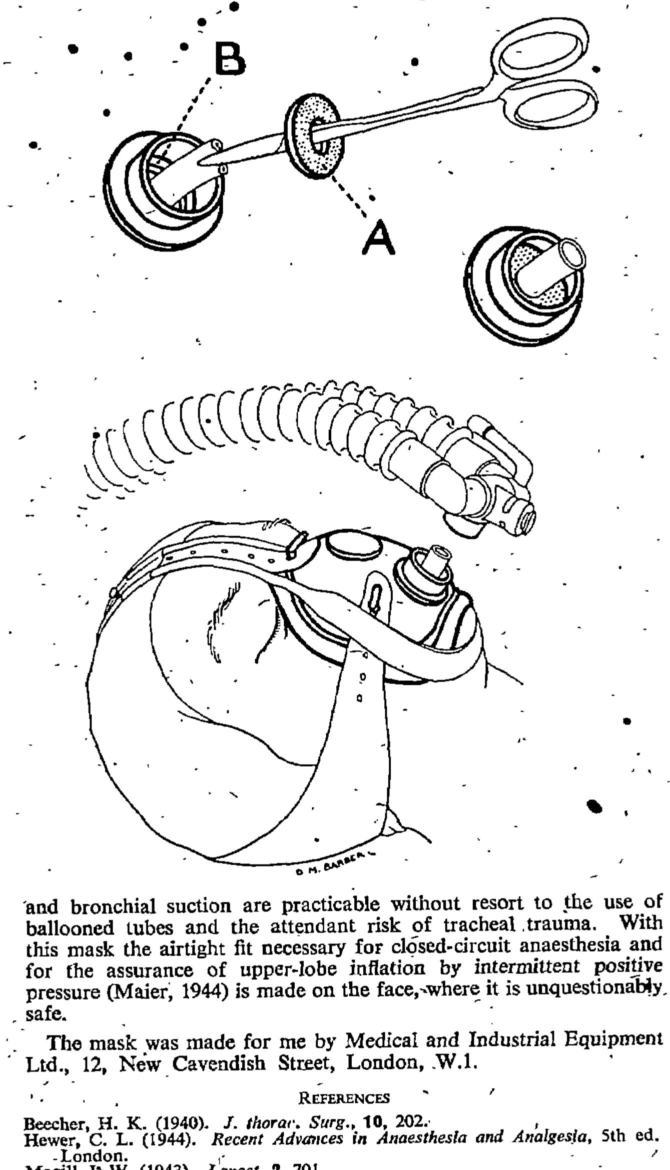
This facepiece facilitates the carrying out of anaesthesia for intrathoracic surgery following the method described by Beecher (1940). The procedure is as follows:

The modified McKesson type mask with a special outlet tube over the mouth, together with preferably Magill's (1943) flexible connector, is used in the ordinary way during induction. After anaesthesia is established the larynx is lightly cocainized by spraying during inspiration with a suitably curved Rowbotham's spray introduced through an oropharyngeal airway. Direct laryngoscopy is performed and a wide-bore Magill's tube passed through the mouth. The tube also may with advantage be sprayed with a little anethaine or 10% cocaine along its distal half immediately before insertion. These manœuvres are sufficient to ensure the smoothness of the subsequent general anaesthesia and supersede formal cocainization of the larynx with its attendant unpleasantness for the conscious patient.

After the tube has been passed a London Hospital airway is threaded over it to give protection against the teeth. In an edentulous patient a Thornton's gag is used. The mask is put on again. With the aid of a Spencer Wells forceps a sorbo washer (A) is threaded over the end of the tube and pushed down until it rests on the flange (B). Magill's connector is then plugged in. The outlet tube of the mask is of such a length that the end of the connector when pushed right home presses the washer firmly against the flange and seals off the joint between intratracheal tube and connector from the cavity of the facepiece and makes it airtight. A Clausen's harness and chin-strap hold the whole assembly firmly in position. With the patient's head extended the intratracheal tube should be long enough to reach from just below the larynx to just above the outlet tube of the mask, as shown in the diagram.

During operation the patient is kept in the Trendelenburg position, and in wet lung cases bronchial secretions run down the trachea and collect in the facepiece. When occasion demands, Magill's connector is unplugged, thus exposing the end of the intratracheal tube, down which a lubricated suction catheter can be easily passed.

The advantages and disadvantages of this type of technique have been fully discussed—Beecher (1940), Nosworthy (1941), Hewer (1944). It is enough to say here that if it is decided to use such a method for lobectomy or pneumonectomy the facepiece described considerably simplifies the practical problems of anaesthetic administration, especially with cyclopropane. Controlled respiration and bronchial suction are practicable without resort to the use of ballooned tubes and the attendant risk of tracheal trauma. With this mask the airtight fit necessary for closed-circuit anaesthesia and for the assurance of upper-lobe inflation by intermittent positive pressure (Maier, 1944) is made on the face, where it is unquestionably safe.



The mask was made for me by Medical and Industrial Equipment Ltd., 12, New Cavendish Street, London, W.1.

The Marriage Guidance Council (78, Duke Street, Grosvenor Square, W.1) held its annual general meeting recently at the Caxton Hall, Westminster. The report for the past year showed that the membership had doubled, that new branches had been formed in the Provinces, and that the London Marriage Guidance Centre had dealt with 650 cases. Opportunity for further extension of the work was hindered somewhat by lack of funds and of office staff. Before this meeting a conference had been held. The first session dealt with "Preparation for Marriage" from (1) the medical, (2) the psychological and spiritual points of view. The value and content of an interview between engaged couples and a doctor were explained by Dr. Lilias Jeffries. The Rev. Gilbert Russell, M.B., B.Ch., spoke of his own method of imparting advice and information. The second session dealt with "Marriage Guidance." Dr. Edward Griffith reported in detail certain cases illustrative of the help that can be given to couples in difficulties. He was followed by Mr. Claud Mullins, the Metropolitan magistrate, who reaffirmed his belief in the value of conciliation work done by trained officers before a couple appeared before the court, where their case would not be considered from its human aspect but argued on its legal basis only.

BRITISH MEDICAL JOURNAL
LONDON
SATURDAY JANUARY 6 1945

PATHOLOGY OF INFECTIVE HEPATITIS

It is a sad illustration of man's unreasoning acceptance of authority that a mistake by Virchow in 1865 should have misled pathologists and clinicians as to the true nature of the lesion in simple or, as he termed it, "catarrhal" jaundice for three-quarters of a century. Bright and Addison were on the right lines in their *Practice of Medicine*, which was published in 1836, when they observed of subacute inflammation of the liver that "cases of the less acute kind . . . generally yield to treatment . . . and they form a large proportion of the cases of simple jaundice which present themselves in practice." This correct view of the place of simple jaundice in nosology was upset by the dictum of the German morbid anatomist, subsequently to be handed from teacher to student and from book to book, that the disease originated in a catarrh of the duodenum which involved Vater's ampulla and led to the plugging of the orifice of the common bile duct with mucus. The story was plausible enough: there were nausea and distaste for food as evidence of gastro-enteritis, the pressure of bile is so low that a mucus plug might well be conceived to obstruct the flow, and there was the asseveration of the Master that he had observed this *in situ*. All this has now gone by the board, and even those who, with the late Sir Arthur Hurst, claimed that on clinical grounds they could differentiate a hepatitic type of jaundice from a "catarrhal" type have now, it is believed, been converted to the view that all forms of simple jaundice—as distinct from gross obstructive jaundice, haemolytic jaundice, and toxic jaundice—arise from a hepatitis.

If this be granted, there still remains the question of whether the hepatitis, which may seemingly be produced in a number of different ways, is a single disease or is capable of differentiation into various types which have in common the symptom of icterus. It is recognized that jaundice of this variety may be sporadic or epidemic, or, as observations scattered over the last ten years have shown, be produced by the injection of human blood, plasma, or serum, in which in some instances an icterogenic agent is present. Into the latter category it seems that "arsphenamine jaundice" must now come—a regular, if capricious, visitant of V.D. clinics which for years has been regarded as a manifestation of an idiosyncrasy to arsenic. The accumulating evidence seems to show that the principal agent in setting up this hepatitis is human blood which has been injected from one patient to another, through a single syringe being used for multiple inoculation without effective sterilization. It is not possible in this brief space to review the evidence of the unity or plurality of hepatitis, but there seem solid grounds for concluding that the type of infection is the same in all cases, and that these may correctly be grouped under the heading of "infective hepatitis." Certainly on pathological grounds—as the biopsy studies of Dible, McMichael, and Sherlock[1] have shown—the hepatic lesion is the same in all instances, which, to put it no higher, is consistent with a like aetiology.

Jaundice has long been recognized as a "disease" apt to occur in epidemics. This characteristic had rather been neglected before the present war, but we find that the American Civil War, the Franco-German War, the Boer War, and the war of 1914–18 all had their epidemics of jaundice. Epidemiologists placed the incubation period round about thirty days, but came to no certain conclusion on the mode of transmission or degree of infectivity of the disease. In all considerable epidemics of jaundice there is a definite low mortality, of between 0.13 and 0.44%, and in the fatal cases there are found in the liver the characteristic changes of acute yellow atrophy. The relation of the severer disease to simple jaundice is clear, and might well have suggested an analogous aetiology and a similar pathological change, but owing to the worship of Virchow this escaped recognition until Eppinger, during the 1914–18 war, had an opportunity to examine the livers of three soldiers who were killed in action while suffering from jaundice, and he described a hepatitis which was likened to acute atrophy in little; there was no obstruction of the bile ducts. The full comprehension of the pathology of acute hepatitis, or acute infective hepatitis, was revealed by the biopsy studies of Roholm and Iverson[2] and the more extensive ones of Dible, McMichael, and Sherlock. These observers, by making sections of small cylinders of liver aspirated from the living patient by means of a hollow needle, were able to construct the picture of the pathological changes present during life and to follow these towards recovery or death. They showed that there is a definite hepatitis, characterized by severe cytological changes and more or less acute necrosis and autolysis of liver cells, leading to a diminution in the size of the lobule and often to a disorganization of the columns of liver cells. Along with this there is a considerable invasion of the lobules, especially of their portal zones, by leucocytes and histiocytes. Successive biopsies revealed that in recovery there is a restoration of the liver even in cases in which disorganization is severe—a complete *restitutio ad integrum*. Where death took place the picture in the terminal stages was one of acute yellow atrophy. Recently a most valuable paper upon the pathology of infective hepatitis and the post-mortem changes in fatal cases has been produced by Lucké.[3] This investigation is based on an analysis of 125 fatalities from over 52,000 cases of the disease in the U.S. Army in 1942. The author divides the condition into pre-icteric, intermediate, and final phases, the duration of the first being about 7 days, of the second about 26 days, and of the last about 10 days. There was no clinical or other indication in the earlier stages that the course of the disease would not end favourably; the final phase was usually ushered in by nervous symptoms (a characteristic noted by Graves in 1843) and associated with ascites and vomiting. Haemorrhages were common in the late period, especially in the intestine and lungs. The changes in the liver were invariably those of acute yellow atrophy, with characteristic red zones of complete liver-cell destruction and survival of vessels, bile ducts, and supporting tissue; and other yellow areas of hyperplastic surviving liver cells, with bile-duct proliferation and an appearance of liver-cell formation from proliferating bile ducts. An additional finding in a number of cases was a phlegmonous inflammation of parts of the gut; this was always associated with ascites and was evidently a terminal phenomenon.

[3] *Amer. J. Path.*, 1944, **20**, 471.

Do these new observations throw light on the mechanism of jaundice in this disease? As there is no obvious lesion and no evidence of bile retention in the main ducts and their interlobular branches, a straightforward obstructive mechanism appears to be ruled out. Lucké supports the view previously put forward by Dible, McMichael, and Sherlock, that there is nevertheless an obstructive element which operates in the intralobular bile canaliculi, found by both groups of observers to contain bile thrombi. It is possible that there may also be some escape of bile into the blood stream in the central areas of the lobules, where the liver cells are most badly damaged and the lobular arrangement most disorganized, and where the cells may be incapable of taking up bile and passing it on to the bile canaliculi.

MITES, ASTHMA, AND ARSENIC

In straightforward asthma the eosinophilia is usually moderate in degree and there are no gross changes in the lungs. There is, however, a series of conditions in which an excessive blood eosinophilia may be associated with changes in the lung fields which are visible in a skiagram. In Löffler's syndrome[1] eosinophilia is associated with transient pulmonary infiltrations. There need be little in the way of symptoms, and the condition clears up spontaneously. Eosinophilic bronchitis[2] is a more serious and persistent disorder in which troublesome cough and asthma-like dyspnoea may be accompanied by lassitude, anorexia, and loss of weight. In the form of eosinophilic bronchitis described by Weingarten in India,[3] now often known as tropical eosinophilia, miliary shadows are seen in the lungs on *x*-ray examination, and the eosinophilia is of a high order, from 40 to 80%. At present it is difficult to define where eosinophilic bronchitis ends and the more serious conditions known as vascular allergy[4] and periarteritis nodosa begin. The latter are generally regarded as morbid responses to bacterial or protein sensitization, and they tend to a fatal issue. The most important discovery in this field has been made by Weingarten, who found that tropical eosinophilia could be cured by a course of injections of neoarsphenamine. Later authors have shown that other forms of arsenic may be equally effective, including acetarsol or carbarsone by mouth,[5] and that arsenical treatment is curative in cases of eosinophilic bronchitis in which the patient has not been in India.[6]

Some cases of Löffler's syndrome have been attributed to the migration through the lungs of the larvae of the roundworm *Ascaris lumbricoides*. In a paper in this issue of the *Journal* it is suggested by Soysa and Jayawardena that tropical eosinophilia is due to pulmonary infestation by mites, or acariasis. The two names "ascaridiasis" and "acariasis" are sufficiently alike to be confused unless care is taken. *Acarus scabiei* is an important parasite in man, and the itch has been one of our wartime worries, but in the absence of secondary infection its effects do not go very deep. Nevertheless more serious diseases are produced by mites in other creatures. Isle of Wight disease in bees, for example, is caused by infestation of the respiratory tract by tarsonemid mites. Carter and his colleagues[7] in Ceylon found mites in the sputum of 17 of 28 patients suffering from chest complaints. The frequency of finding of mites was proportional to the time that could be devoted to the examination and the number of specimens examined, for the mites are neither frequent nor constant. Even when collections consisting of 5 to 40 c.cm. of sputum were examined it was unusual to find more than one or two mites in any one sample. The mites found were similar to those which could be demonstrated in the dust of the hospital and the laboratory, the bedding of patients, and similar situations. They were not contaminants of the sputum, as great care was taken to exclude this source of error; nor were they mere air-borne transients in the bronchial tree, for in some cases all stages from eggs to adults were demonstrated. Carter and his colleagues thought the evidence suggested strongly that the mites were not just living in the bronchial tree as commensals but that they were actively pathogenic and responsible for the bronchial irritation and the eosinophilia. Soysa and Jayawardena have now collected 30 cases of eosinophilic bronchitis in Ceylonese soldiers, all of whom did well on oral treatment with acetarsol or carbarsone. Improvement was often preceded by a temporary exacerbation of symptoms, a phenomenon noted by others. Mites were found in 11 out of the 21 patients whose sputum was examined by the special technique of Carter and co-workers, and the authors conclude, like Carter, that a proportion of cases of tropical eosinophilia are due to the pathogenic effects of mites. Most of the patients were working in proximity to ration stores or equipment depots, where mites were numerous

It is clear that eosinophilic bronchitis is much commoner in the Tropics than had been realized, and that arsenic is effective in treatment. The part played by the mite is more controversial. The presence of excessive secretion in the asthmatic bronchus favours the growth of bacteria and moulds, and certain types of Gram-negative bacilli and yeasts, which are almost certainly saprophytic and the result of the asthma, are sometimes found in pure culture. Mites are evidently common in the atmosphere of Ceylon, and they might therefore be expected to colonize the airway in eosinophilic bronchitis. It is even possible that the mite acts as the vector for the specific agent of tropical eosinophilia. If the mite is the primary cause of the illness it is a little difficult to understand the therapeutic action of arsenic, which is not particularly effective against mites. Moreover, one would expect to get positive skin reactions with extracts of materials heavily infested with mites. A more practical question for the doctor in this country concerns the criteria for the diagnosis of eosinophilic bronchitis and the selection of patients for treatment with arsenicals. In a typical example the asthma is of the acquired type, and there is no family history of asthma or previous history of allergy. The total eosinophil count is over 4,000 cells per c.mm. and the percentage over 30. The *x*-ray appearances in the lungs are said to be almost pathognomonic. Only when these criteria are fulfilled would it seem desirable to submit patients to vigorous treatment with a toxic drug such as arsenic.

ARSENIC IN THE TREATMENT OF MALARIA

The cinchona alkaloids, and especially quinine, have until recently held the field as being for all practical purposes the only specific remedies against malaria, and treatment consisted almost entirely in the dosage and methods of administering quinine. This traditional view was modified when plasmoquine and then atebrin (mepacrine) had been shown to be equally specific in their action, and there began a period of search over wide fields for new and possibly more effective antimalarial drugs. The problem was not entirely or even mainly one relating only to effectiveness against the acute attack. That the ordinary attack of malaria can be clinically cured by either quinine or mepacrine has long been established. But there are directions in which these drugs are not always capable of performing all that is desired of them. This is particularly so in the failure as a result of treatment to eliminate that most troublesome characteristic of malaria—the liability to relapses. In a recent letter to this *Journal*[1] Capt. R. Good has suggested that arsenical treatment might be tried in cases of naturally acquired malaria which do not respond to quinine, etc., having found that in induced malaria (*vivax* infection) a single intravenous injection of neokharsivan (0.45 g.) invariably cut short the attacks without subsequent relapses. In another letter[2] Prof. Blacklock pointed out that in 1917–20 in a long series of studies in the treatment of malaria a team of workers at the Liverpool School tested, among other drugs, arsenicals of the novarsenobillon type, as well as liquor arsenicalis alone and in combination with strychnine or quinine. The cases treated were long-standing infections which had relapsed frequently in spite of much treatment with quinine. The immediate effect of the arsenobillon on *Plasmodium vivax* was strikingly good, being even more rapid than that of quinine in causing all forms of the parasite to disappear. The ultimate results, however, were disappointing, as practically all the cases relapsed, even after a dose of 0.9 g. In *falciparum* and *malariae* infection arsenobillon in the same dosage was not much use.

The experiments referred to by Prof. Blacklock are not the only ones leading to the same conclusions—viz., that, although the intravenous injection of arsenicals may lead to rapid clearing of the parasites from the blood in *vivax* malaria, it has little or no effect against *falciparum* and *malariae* infection. Moreover, arsenicals, though immediately effective against the *vivax* parasite, do not eliminate the liability to relapses. Goldman,[3] in 1938, found that in 90% of cases a single injection of 0.4 to 0.6 g. of mapharsen sufficed to terminate *vivax* malaria permanently, and the same claim seems implicit in Capt. Good's letter. The important point here, which is not stressed, is whether these results in respect of subsequent relapses were obtained with cases infected by blood inoculation or by the bite of infected mosquitoes. Both S. P. James[4] and Warrington Yorke[5] have drawn attention to the marked difference in reaction to treatment under these two conditions. Both agree as to the non-liability to relapse after even the mildest treatment in cases in which malaria has been induced by blood inoculation, but not in mosquito-infected cases. It is also important to recognize that the effect of intravenous arsenic appears to be entirely confined to *vivax* infection, so that its usefulness for treatment of malaria in the Tropics would be limited. Administration of mapharsen or other arsenical compounds would appear at present to find little place in the treatment of malaria, though it may have a use in special cases.

LIVESTOCK FERTILITY

The fertility of farm animals can be increased by raising the number of young born in each litter or by producing heat and conception outside the normal breeding season. In 1940 Parkes and Hammond[6] reported preliminary results of their efforts to use gonadotrophic extracts for this purpose. Injections of horse pituitary extract into ewes during anoestrus brought on oestrus, though the ewes would not accept the ram until given a second injection 15 to 17 days later. Of 7 ewes so treated 4 became pregnant, and 7 lambs were the result. The number of ova shed after such treatment was within the normal range. During the breeding season superovulation was induced by injections in the last 3 to 4 days of the cycle—that is, in the follicular phase. As many as 9 ova were shed by one animal, and up to 7 fertilized eggs were recovered. In one instance 5 embryos were still present half-way through pregnancy. More extended results published later[7] showed that pregnant mares' serum or oestrogen would also cause normal ovulation in anoestrous ewes, but heat did not follow the gonadotrophin injections except in the presence of a regressing corpus luteum. In oestrous animals the presence of an active corpus luteum appeared to suppress both ovulation and heat, but superovulation, with as many as 12 ova, was obtained by giving horse-pituitary gonadotrophin a few days before the corpus luteum was due to regress. In cows and heifers Hammond and Bhattacharya[8] stimulated ovulation in a majority of cases by giving 1,500–5,000 i.u. of pregnant-mare-serum gonadotrophin from 5 days before to 3 days after manual expression of the corpus luteum from the ovary. As many as 30 ovulations in a single animal were obtained, but in a small series that were allowed to go to term the number of young born was within normal limits, though twins and triplets were abnormally frequent. Folley and Malpress[9] find that the threshold dose of serum gonadotrophin necessary to stimulate the ovary is 1,000–2,000 i.u., while maximal responses are evoked by injections of 3,000–4,000 i.u. Ovulation was produced only during the follicular phase, though horse-pituitary gonadotrophin was effective in this respect at all stages of the cycle.

In America a group of workers in the University of Wisconsin have carried out similar researches on cows and sheep. Subcutaneous injections of unfractionated or follicle-stimulating extracts of sheep pituitary, followed by intravenous injection of a luteinizing extract from the same source, brought on ovulation in calves and cows. The eggs shed in this fashion were fertilizable, but only in an abnormally small percentage of cases. In the cows such injection procedures during the breeding season only increased fecundation when given in the second half of the cycle, and there was evidence of early foetal death in such hyperfecundation. In sheep, Warwick and Casida[10] brought about superovulation by a similar series of injections, though only when given in the follicular phase of the cycle. When the injections were made in the luteal phase of the cycle or during anoestrous, ovulation was consistently produced but oestrus was not, while variations were noted in attempts to fertilize the shed eggs by artificial insemination.[11] Eggs shed during the luteal and anoestrous phases were all unfertilized, while of 24 ewes treated during the follicular phase 7 had no fertilized eggs. The total number of eggs recovered was 357, and in the 17 animals in which fertilization took place there were 153 fertilized eggs.[12] Failure to maintain hyperfecundation was also confirmed by subsequent mating or artificial insemination of ewes in which superovulation was produced by the usual injections during the follicular phase. The average number of embryos per ewe was 9.2 at 2 to 5 days, 3.4 at 14 to 27 days, and 0.8 at 30 to 37 days.[13]

Present results show that it may be possible to work out methods for inducing out-of-season breeding, but that hyperfecundation, if produced, is not maintained, and that the number of young can be increased only by increasing the incidence of twin and triplet births. The value of these investigations is, however, not confined to their practical outcome on the farm, for they also help in the elucidation of normal ovulatory mechanisms; this must be completed before we can hope for any general success in the treatment of human infertility.

DIASONE IN TUBERCULOSIS

It does no harm to recall that it was Buttle in this country who introduced the diphenylsulphones as chemotherapeutic agents. Diasone is the disodium formaldehyde sulphoxylate derivative of 4-4′diamino-diphenylsulphone, a compound synthesized by Raiziss. It is related to promin, which was shown by Feldman, Hinshaw, and Moses[14] to be of value in the treatment of tuberculosis in guinea-pigs. Petter and Prenzlau[15] have now described their results with diasone in 44 patients, and it must be admitted that these do not look unpromising.

All the patients received diasone for 120 days or more, and the majority for 164 days. The total daily dose was 1 g. There appear to have been no serious reactions. The drug made about half of the patients feel tired and listless at first, and those with fresh exudative lesions had an initial rise of temperature. One patient developed a skin rash: it is interesting to note that by withholding the drug for a few days and then slowly increasing the dose from 0.1 g. per day she was finally able to take 0.66 g. a day without a reaction. There was some cyanosis, and nausea in about one-quarter of the patients; vomiting was rare. Some patients suffered from headache and photophobia, but these symptoms diminished. There were no renal symptoms or signs, and there was no leucopenia or agranulocytosis. The haemoglobin value and red cell count fell, however, particularly in the second to fourth weeks, when the composite haemoglobin figure had dropped from 12.5 g. to 8.7 g. per 100 c.cm. It is true that the haemoglobin rose again, and by the twenty-first week had reached 11 g. per 100 c.cm., but certainly the drop is alarming. The patients were radiographically examined beforehand, and sputum analyses were made. Most had already had the usual sanatorium treatment without making progress. No collapse therapy was undertaken during administration of the drug, and 18% were not confined to bed.

Signs of improvement were seen as follows: Between 45 and 125 days 60% of the group became sputum-negative. This occurred in all the lighter cases and in two-thirds of the moderately advanced group. Even one-third of the far-advanced group became negative. The sputum examination was thorough. In 34 of the 44 patients the sedimentation rate fell from a mean value of 45 mm. per hour to a mean value of 11 mm. per hour in 25 weeks. *X*-ray examination showed that some resolution of infiltration occurred in 90%. Of the cavities present before therapy 43% disappeared. The authors consider they observed marked improvement in 18% and moderate improvement in 50%. They present their evidence plausibly, emphasizing the fallacies. They reach what appears to be a justifiable conclusion that "diasone points the way to further advances in the treatment of tuberculosis in man."

THE WALTER AND ELIZA HALL INSTITUTE

A quarter of a century has now passed since the Walter and Eliza Hall Institute of Research in Pathology and Medicine began to function in Melbourne, three years after its foundation in 1916. The twenty-fifth annual report is signed by Dr. F. M. Burnet, F.R.S., a distinguished worker in the field of medical science who in March last succeeded Dr. C. H. Kellaway, F.R.S., as Director when Dr. Kellaway came to England to take up the post of Director-in-Chief of the Research Laboratories of the Wellcome Foundation. Dr. Burnet records that for 20 years Dr. Kellaway guided and developed the Institute to its present status. When he took over in 1923 a useful foundation had been laid, but the subsequent expansion of the activities and the reputation of the Institute were due wholly to his scientific ability, his enthusiasm, and his skill and wisdom in human contacts. In the interval between Dr. Kellaway's appointment by the Wellcome Foundation and his departure from Melbourne an invitation to deliver the Dunham Lectures at Harvard Medical School gave Dr. Burnet an opportunity to visit laboratories in the United States and Canada before taking over the directorship. The subject of these and his other lectures in America was research in virus disease. The work of the Walter and Eliza Hall Institute has continued to be directed mainly towards problems concerned with the medical aspects of the war. With the impending transfer of the Royal Melbourne Hospital to the new buildings in Parkville it will again be possible to have a closer association between the Institute staff and those concerned with the routine pathological and biochemical services. During the year under review most of the work of the Virus Department again centred round the problems of influenza in its relation to Army personnel. Until he left for England Dr. Kellaway, in collaboration with Mr. W. A. Rawlinson, continued his studies on heat injury in the Physiology Department. Mr. H. F. Holden's work in the Biochemical Department has again been largely concerned with investigations required by the Services. The Institute carried out blood grouping for the Services in Victoria, but on a smaller scale than in the previous year. Blood tests have also been made, as before, on donors for the Red Cross Transfusion Service and the Blood Bank. Serological work has been expanded to include research on the Rh factor and the setting up of a large enough panel of Rh-negative donors.

RESUSCITATION METHODS FOR RESCUE BOATS

BY

F. C. EVE, M.D., F.R.C.P.

Resuscitation is in the melting-pot. We have lost our old confidence that if Schäfer's ritual is faithfully performed nothing better can be done. We now realize that resuscitation is a trinity—of ventilation of the lungs, warmth, and restoring circulation to the nerve cells of the brain, of which the last is often the most important. For the circulation, Silvester's method appears to be better than Schäfer's, and the rocking method (Eve, 1932) much the best on present evidence (Hemingway and Neil, 1944). Ventilation is adequate by the older methods in mild cases, but not in bad cases when chill, delay, and asphyxia have nearly killed the vital nerve cells. Then the diaphragm loses tone, stretches, and is pulled up by the elastic lungs into a contracted condition of extreme expiration. At that stage Schäfer's method is impotent: no air will enter or leave the lungs, which obviously need expansion, not compression. But the rocking method, in which the weight of the abdominal contents pushes and pulls the diaphragm up and down like a piston, still acts perfectly—being independent of muscular tone. These considerations led the Royal Navy (in which the results of the Schäfer method had been very disappointing) to adopt the rocking method when possible (Gibbens, 1942).

This, very briefly, is the present position, which rescuers should know. Evidently it is in the rescue-boat that lives can be won or lost: the victim may be too far gone for resuscitation by any method by the time that ship or shore is reached. This problem has never been systematically studied, and it is different for each type of boat. The men who will man the boat in an emergency must try out *beforehand* the method best suited to their boat and submit their plans to an appropriate doctor. For instance, the seats may be too short or crowded to permit Schäfer's method; the thwarts may be too deep or the floorboards too wet for the older manual methods. I am told that in a speed-boat the thumping on the waves makes Schäfer impossible, and hence the rocking method is being substituted by the R.A.F. Cmdr. Michelmore took me a trip in the smaller type of National Lifeboat. It was so cluttered with necessary gear that we agreed that to make a flat place with life-jackets for Schäfer's method was the only solution.

I now submit two methods which seem worthy of trial under actual rescue conditions: (1) manual rocking (Eve, 1943); (2) the Lap-Silvester method (Eve, 1944).

(1) The Manual Rocking Method, as applied in a Rescue-boat (Figs. 1–3)

Two men stand facing, gripping each other's hands (or, better, a bandage twisted into a small ring). The victim lies face downwards across the two pairs of linked forearms, which support his thighs and upper chest. His arms and head dangle limply. It is preferable for each bearer to place his forearm under both thighs and grip the trousers, as photographed. The two men, by swaying from their hips, rock the casualty through about 45° each way, starting head down and pausing till all water has drained out before inducing inspiration by the feet-down tilt. This rocking is continued 10 or 12 times a minute till the patient breathes naturally, when he can be laid down, prone at first. This was done to me in a very large ship's lifeboat. I did not have to breathe, so the ventilation must have been adequate. The stalwart pair said they could have rocked my 10½ st. easily for a quarter of an hour at least. A heavy casualty would be unsuitable: a child can be rocked by one person. I believe that with their legs astride a thwart the two operators (now linked into a quadruped) will have considerable stability. In a sea-way they could sit down if preferred (Fig. 3).

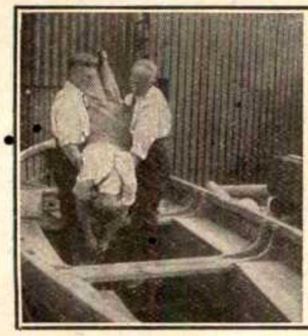

FIG. 1

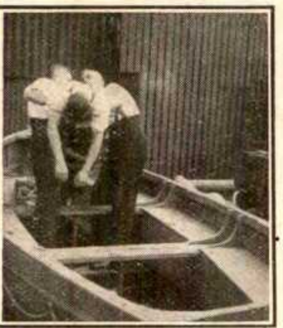

FIG. 2

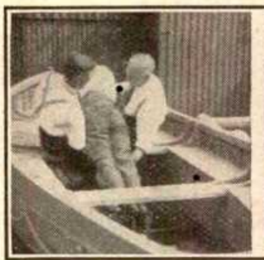

FIG. 3

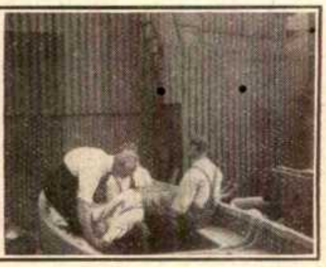

FIG. 4

A Child Revived by Manual Rocking.—A little girl of 4 was immersed for some 5 minutes in the pit of a stationary mill-wheel near Truro last Easter. Pte. Jack Collings descended, and also slipped into the water. At once he performed manual rocking through quite 45° a dozen times a minute. In the confined space this was the only prompt method. Respirations returned in 10 or 15 minutes, and recovery was complete. The first head-down tilt emptied at least half a teacup of water through the mouth. Fortunately, in his first-aid class, the operator had himself been rocked on the usual rocking stretcher. So that the credit of this first resuscitation by *manual* rocking must be shared with his instructor, Supt. Schoon, who supplied me with these particulars.

(2) The Lap-Silvester Method (Fig. 4)

This idea was originally suggested to me by the ladies of the Tunbridge Wells Red Cross (Dr. Taylor's class). The casualty lies face upwards on the laps of two bearers sitting on a thwart (oilskin trousers donned on the outward trip). It is better that they should face opposite ways so that the victim is oblique to the thwart. The operator stands astride the thwart and uses Silvester's method, grasping the forearms and alternately extending them horizontally, and compressing the chest with them, firmly but not violently. (There is no room for the orthodox outward sweep of the arms, which I fancy, after personal trial, is redundant.) The thigh of the first sitter gives room for the head to dangle right back, a posture in which one throat specialist assures me the tongue will not block the glottis. This is confirmed by the radiograph of the airway of a young adult in this posture, kindly taken by Dr. Bannen. The first sitter flexes the neck during expiration so that the brain is alternately congested and emptied of blood (important for its circulation). As necks vary, he should also watch the tongue in inspiration. The second sitter during expiration leans his weight forward so that his forearm compresses the abdomen (more effectual than the hand). This pushes up the diaphragm and also propels blood from the abdomen to the heart. This method is available if the victim is too heavy or the rescue-trip too long for manual rocking.

Dr. R. R. Macintosh, Nuffield Professor of Anaesthetics, investigated this method at Oxford and kindly allows me to quote the unpublished results. Mr. J. Roberts, a healthy athlete, submitted altruistically to anaesthesia with apnoea caused by hyperpnoea, in which the state of drowning was simulated. The ventilations produced by each rock (ten a minute) through 45° each way on a stretcher were: Schäfer, 530 c.cm.; Silvester, 650; rocking, 850 c.cm. These figures confirm the previous (Macintosh, 1943) historic experiment on Squad. Ldr. A. E. Pask, which are proportionally similar (340, 400, and 580 c.cm.), and were done by the same team of experts. Rocking Mr. Roberts face upwards was less effective than prone (570 c.cm. at 30°; 635 at 45°). If the piston action of the diaphragm was impeded by a pillow under the abdomen, rocking face downwards was only half as efficient (325 c.cm. con 725 at 30°). An interesting novelty was the excellent ventilation produced (630 and 670 c.cm.) by merely lifting the pelvis or coat when prone, thus allowing the abdomen to sag and pull down the diaphragm. (This should be useful to remember when doing the Nielsen modification of Schäfer.)

The *Lap-Silvester*, done on two laps with straightish spine (too much bent in Fig. 4), gave the adequate ventilation of 530 c.cm. improved to 600 c.cm. by abdominal pressure (cf. Schäfer, 530 c.cm.). With a Beverley team, I saw that the Lap-Silvester method is practicable in a 6-oared ship's lifeboat of 6-ft. beam (Fig. 4). Its merits are: warmth and dryness on laps; ventilation proved adequate; the dangling head should obviate traction on tongue or jaw; adequate abdominal compression for diaphragm and circulation; alternate congestion and emptying of cerebral blood vessels (probably important). Hence this method seems worthy of trial in a rescue-boat, but neck or spine must never be forced backwards.

Summary of Conclusions

1. Resuscitation must be started *immediately* the victim is hauled aboard over the lee stern quarter: ship or shore may be too distant for revival. Water must first be drained out by a steep head-down tilt (Fig. 1).

2. If space allows, Schäfer may then be used provided that air can be felt or heard going in and out of the mouth.

3. If this is not satisfactory, or resilience feels absent in the lungs, do not persist in the Schäfer ritual, but change at once to the manual rocking method, especially in a child or light subject. Personally, I would start with this method, after draining out water.

4. For heavy subjects or longer boat-journeys, the Lap-Silvester method is suggested as being warmer and providing more circulatory aid to the brain and heart than plain Silvester or Schäfer.

5. Rescue-boats differ greatly; each type is a separate problem in methods of resuscitation, which need to be tried out *beforehand* by rescue teams who dwell beside deep waters.

Methods must be judged by records of successes and failures, which I should be glad to collect and collate until there is some official channel.

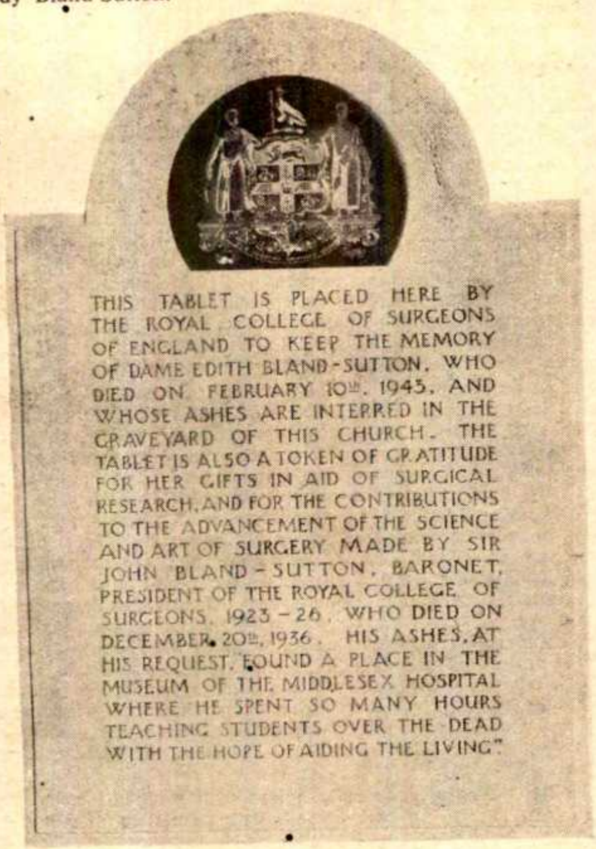
A BLAND-SUTTON MEMORIAL

At the instance of Sir Alfred Webb-Johnson, President of the Royal College of Surgeons, we are able to reproduce below a photograph of a mural tablet in memory of Sir John and Lady Bland-Sutton.



THIS TABLET IS PLACED HERE BY THE ROYAL COLLEGE OF SURGEONS OF ENGLAND TO KEEP THE MEMORY OF DAME EDITH BLAND-SUTTON, WHO DIED ON FEBRUARY 10TH, 1943, AND WHOSE ASHES ARE INTERRED IN THE GRAVEYARD OF THIS CHURCH. THE TABLET IS ALSO A TOKEN OF GRATITUDE FOR HER GIFTS IN AID OF SURGICAL RESEARCH, AND FOR THE CONTRIBUTIONS TO THE ADVANCEMENT OF THE SCIENCE AND ART OF SURGERY MADE BY SIR JOHN BLAND-SUTTON, BARONET, PRESIDENT OF THE ROYAL COLLEGE OF SURGEONS, 1923-26, WHO DIED ON DECEMBER 20TH, 1936. HIS ASHES, AT HIS REQUEST, FOUND A PLACE IN THE MUSEUM OF THE MIDDLESEX HOSPITAL WHERE HE SPENT SO MANY HOURS TEACHING STUDENTS OVER THE DEAD WITH THE HOPE OF AIDING THE LIVING."

A Faculty has been granted by the diocesan authorities of Canterbury for the erection of this tablet in the Parish Church at Ringwould, Kent, where Sir John and Lady Bland-Sutton regularly worshipped when they were in residence at Villa Vita, Kingsdown, Deal. The memorial was designed by Alner W. Hall, *M.C.*, F.R.I.B.A.

KING EDWARD'S HOSPITAL FUND

The Speaker of the House of Commons presided, in the absence of the Duke of Gloucester, at the meeting on Dec. 11 of the general council of the King Edward's Hospital Fund for London. He referred in his opening address to the discussions which representatives of the Fund, "with their impartial and at the same time intimate knowledge of so many hospitals," had had with the Minister of Health, and to the help this would mean to the Minister in framing his proposals. Work on hospital diet was, he added, very much to the fore, and Sir Jack Drummond and his committee were now preparing a second memorandum offering more detailed advice based upon the experience of surveys at a good many hospitals.

Sir Edward Peacock as treasurer reported that in view of the heavy expenditure which would confront the hospitals after the war it had been thought wise to continue the slight reduction in the annual distribution, which was again £280,000. Subscriptions and donations, estimated at £38,000, were about the same as last year. Income from investments, at £213,000, showed an increase of £10,000 over the previous year, but this included certain arrears and other non-recurring items. These figures did not include the £300,000 received from the Nuffield Trust for the special areas and the transfer from this amount of £250,000 to Guy's Hospital.

Speaking of plans for a national health service, Sir Edward said that during the summer a statement of principles was prepared in close concert with the Voluntary Hospitals Committee and the British Hospitals Association, which underlined the meaning of partnership between voluntary and municipal hospitals, laid stress upon the need for a Central Hospitals Board and on regional and local machinery, dealt with the financial issues raised by the White Paper, and pointed out the importance of making it quite clear that payments from public moneys would be payment for services and not subsidies. The proposal of the White Paper, he continued, that all hospital services should be free of necessity cut at the roots of the contributory schemes which had become such a valuable feature of the life of this country. Everything must be done to preserve as large a part of the voluntary support of hospitals through such schemes as was possible. It would be almost criminal if, in our endeavour to secure another valuable thing, we should destroy that unique organized contribution of millions of pounds by millions of people to their hospitals.

The Public Instinct about Hospitals

Sir Alfred Webb-Johnson, in proposing a vote of thanks to the Speaker, said that the instinct of the people had been sound in regard to the type of hospital which the people had built for themselves—the great general and special hospitals, which acted as centres for consultation; the intermediate type of hospital, which served the immediate needs of a populous area; and the home or cottage hospital, which met the needs of the general practitioners in the smaller communities. This instinct had also been sound on the distribution of hospitals. The great consultant hospitals were based on university centres and their influence spread over large areas. People went to these consultation centres not because of any geographical arrangement, but because they served natural "catchment areas." National or county boundaries did not count; when a man was sick and his people were anxious about him they wanted to go where facilities were best and where the advice they sought was accessible and available. In the management of the voluntary hospitals the instincts of the people had again been sound. They had given absolute freedom to the professional men who work in the hospitals, had sought their advice in their corporate capacity through the medical committees, and had sought their aid in the management of the hospitals.

But in spite of all this there was need for more co-ordination and expansion, and it was to be hoped that the Government would follow the example of the King's Fund, and would guide and not control, would help the voluntary hospitals and not hinder them. It was important that the contributions under the National Health Insurance scheme, which were not really enough to meet the general practitioner service, should be devoted entirely to that service, and that the hospitals should be maintained by rates, taxes, and voluntary contributions. This would do something to preserve the voluntary contributions, because insured persons would not be told that they had already subscribed directly to the voluntary hospitals.

The people of this country must retain the advantages which they had gained for themselves, and the way to do this was for experts in hospital matters to have a responsible part in the planning and administration of the hospital services. Those experts—the representatives of the voluntary hospitals and representatives of the medical profession—must have their place in the council chamber.

In conclusion Sir Alfred spoke as follows: "When we talk about the freedom of the profession we are not talking about some vested interest. We are talking about one of the fundamental liberties of the subject—his right, within a free community, to obtain free and independent advice from professional men, whether it be in law, medicine, or any other profession. The people are entitled to a free professional opinion. This implies freedom for independent practice. In specialist work the natural place for independent practice is within the precincts of hospitals. I hope that in future nothing will be put in the way of independent practice inside hospitals or in the precincts of hospitals. It would be a retrograde step if that independent practice were to be dispersed into separate clinics."

The vote of thanks was seconded by Sir Henry Tidy.

NEW YEAR HONOURS

The names of the following members of the medical profession were included in a New Year Honours List published in a *Supplement* to the *London Gazette.*

Baronetcy

Sir Alfred Webb-Johnson, K.C.V.O., C.B.E., D.S.O., President of the Royal College of Surgeons.

K.C.B. (Military Division)

Sir Harold Edward Whittingham, K.B.E., LL.D., K.H.P., F.R.C.P., Air Marshal, R.A.F.

Knighthood

Arthur Murray Cudmore, C.M.G., M.B., F.R.C.S. Colonel. President of the Medical Board of the State of South Australia. For public services.

Claude Howard Stanley Frankau, C.B.E., D.S.O., M.S., F.R.C.S. Director, Emergency Medical Services, London and Home Counties.

Alfred Bakewell Howitt, C.V.O., M.D. Member of Parliament for Reading since October, 1931. For political and public services.

Diwan Bahadur Arcot Lakshmanaswami Mudaliyar, LL.D., M.D., D.Sc. Vice-Chancellor, University of Madras.

Lionel Ernest Howard Whitby, C.V.O., *M.C.*, F.R.C.P. Brigadier, Territorial Army, Reserve of Officers; lately Bacteriologist, Middlesex Hospital. For services in development of the sulphonamide group of drugs.

C.B. (Military Division)

Andrew Grant, C.B.E., M.B., K.H.S. Air Vice-Marshal, R.A.F.

David Turnbull Richardson, *M.C.*, M.B., K.H.S. Major-General, R.A.M.C.

William Ross Stewart, C.I.E., M.B., F.R.C.S., K.H.P., V.H.S. Col. (Temp. Brig.), I.M.S.

C.S.I.

John Simon Stuart Martin, M.B., M.R.C.P., K.H.S. Major-General, I.M.S., seconded I.A.M.C. Deputy Director of Medical Services, Central Command, India.

C.M.G.

Henry Spelderwinde de Boer, *M.C.*, M.R.C.S., D.P.H., D.T.M.&H. Colonial Medical Service; Director of Medical Services, Uganda.

William Ellis, Lieut.-Col., R.A.M.C. (ret.). Press Attaché at His Majesty's Consulate-General, Tangier.

C.I.E.

Rai Bahadur Tridib Nath Banarji. Principal, Prince of Wales Medical College, Patna, Bihar.

Donald MacDonald Fraser, M.B. Lieut.-Col. (Local Brig.), I.M.S., seconded to I.A.M.C. Inspector of Medical Services, General Headquarters, India.

William Calder Paton, *M.C.*, M.B., F.R.C.S.Ed. Major-Gen., I.M.S. Surgeon-General with the Government of Bengal.

C.V.O.

Walter Graham Scott-Brown, M.D., F.R.C.S.

C.B.E. (Military Division)

Thomas Benjamin Dixon, M.R.C.S., K.H.P., V.D. Surg. Capt., R.N.V.R. (ret.).

Edward Cyril Knowes Henry Foreman, M.R.C.S. Gp. Capt., R.A.F.

John Struthers Fulton, M.D., M.R.C.P. Col. (Temp. Brig.), R.A.M.C., T.A.

C.B.E. (Civil Division)

Mrs. Mary Georgina Blacklock, M.B. Lecturer, Liverpool School of Tropical Medicine.

Hugh Ernest Griffiths, M.S., F.R.C.S. Surgeon, Albert Dock Hospital, and founder of the Fracture Clinic and Rehabilitation Centre.

Thomas Baillie Johnston, M.D. Superintendent and Professor of Anatomy, Guy's Hospital; Sector Hospital Officer, Emergency Medical Services, London.

James Rognvald Learmonth, Ch.M., F.R.C.S.Ed. Surgical Director, E.M.S., South-Eastern Area of Scotland; Professor of Surgery, Edinburgh University.

Alfred Alexander Webster Petrie, M.D., F.R.C.P. Lieut.-Col. Medical Superintendent, Banstead Mental Hospital.

George Blyth Walker, M.B., D.P.H. Colonial Medical Service; Deputy Director of Health Service, Nigeria.

O.B.E. (Military Division)

Joseph Alexander Bingham, T.D., M.B., F.R.C.S.Ed. Lieut.-Col. (Temp. Col.), R.A.M.C.

Thomas Francis Crean, L.R.C.P.&S. Surg. Cmdr., R.N.

Agnes Lilias Dovey, M.B. Squad. Ldr. Employed with R.A.F. Medical Branch.

George Harvey Duthie, M.B. Acting Squad. Ldr., A.A.F.

Richard White Bernard Ellis, M.D., F.R.C.P. Acting Wing Cmdr., R.A.F.V.R.

William Loren Fennell, M.D. Lieut.-Col. (Acting Col.), I.M.S.

Leslie Fletcher, M.B. Major (Temp. Lieut.-Col.), R.A.M.C.

John Cary Gilson, M.B., M.R.C.P. Squad. Ldr., R.A.F.V.R.

Thomas James Myles Gregg, M.B. Acting Wing Cmdr., R.A.F.O.

Cecil William Kidd, M.D. Acting Wing Cmdr., A.A.F.

Ian Morrison Orr, M.D., M.Ch., F.R.C.S. Major (Temp. Lieut.-Col.), R.A.M.C.

Basil Gerald Parsons-Smith, M.R.C.P. Acting Squad. Ldr., R.A.F.V.R.

James Frederick Sandow, M.R.C.S. Acting Gp. Capt., R.A.F.

Norman Ralph Smith, M.R.C.S. Acting Wing Cmdr., A.A.F.

James Elliott Snow, M.R.C.S. Major (Temp. Lieut.-Col.), R.A.M.C.

Thomas James Logan Thompson, *M.C.*, M.B. Lieut.-Col. (Temp. Col.), R.A.M.C.

Edward James Starbuck Woolley, M.B. Surg. Lieut.-Cmdr., R.N.V.R., late Senior Naval Officer i/c Naval Detachment Station, Tristan-da-Cunha.

O.B.E. (Civil Division)

Arthur Edgar de Chazal, M.S., F.R.C.S. For public services in Mauritius.

Peter Alphonsus Clearkin, M.D., D.P.H. Colonial Medical Service; Government Bacteriologist and Pathologist to Public Hospital, British Guiana.

Keith Simpson Fitch, F.R.C.S.Ed. Lieut.-Col., I.M.S. Deputy Surgeon-General, Famine Relief, Bengal.

Anastasios Gavrielides, Consulting Surgeon, Medical Department, Cyprus.

Roy Mervyn Humphreys, D.M. Senior Physician, Sudan Medical Service.

Alan Alexander Pullar, M.B., F.R.C.S. Major, I.M.S. Presidency Surgeon, Bombay.

Wenefride Thompson, M.B.E., M.R.C.S. St. Luke's Mission Hospital, Lakhimpur, Dibrugarh, Assam.

The Rev. Felix Gordon Veitch, M.D. For public services in Jamaica.

M.B.E. (Military Division)

Avyaktanand, Capt. (Temp. Major), I.A.M.C.

Hannah Billig, *G.M.*, M.B., B.S. Capt., I.M.S.

Kollemparampil Eapen Eapen, Lieut., I.A.M.C.

Emmie Dorothy Fenwick, M.R.C.S. Squad. Ldr. Employed with R.A.F. Medical Branch.

Oliver Garrod, M.R.C.S. Capt., R.A.M.C.

Geoffrey Hale, M.B. Fl. Lieut., R.A.F.V.R.

Thomas Theodore Schoales Hall, M.D. Major, R.A.M.C., T.A.

James Harper, M.B. Fl. Lieut., R.A.F.V.R.

Edward Watson Hart, M.B., M.R.C.P. Capt. (Temp. Major), R.A.M.C.

Gwilym Murray Jones, M.R.C.S. Fl. Lieut., R.A.F.V.R.

Andrew Derek Kelly, M.B Capt. (Temp. Major), R.A.M.C., T.A.

Albert James Lawlor. Capt. (Temp. Major), R.A.M.C.

Abdul Hague Mallick. Capt. (Temp. Major), I.A.M.C.

Malcolm John May, M.R.C.S. Temp. Surg. Lieut., R.N.V.R.

William d'Auvergne Maycock, M.D. Capt. (Temp. Major), R.A.M.C.

Edward James Pell. Capt. (Temp. Major), I.A.M.C.

Athol George Riddell, M.R.C.S. Acting Squad. Ldr. R.A.F.V.R.

Alexander Skene, M.B. Fl. Lieut., R.A.F.V.R.

Alastair William Smith, L.R.C.P.&S. Temp. Surg. Lieut., R.N.V.R.

Vernon Donald Van Someren. Capt. (Temp. Major), E.A.A.M.C.

Derek John Wigginton, M.R.C.S. Capt. (Temp. Major), R.A.M.C., T.A.

Harold Geoffrey Wolskel, M.R.C.S. Fl. Lieut., R.A.F.V.R.

M.B.E. (Civil Division)

Ramiro Cauchi Inglott, District Medical Officer, Malta.

Sharat Shashi Kundu, M.B. Officiating Civil Surgeon, Manipur State, Assam.

William Cecil Wigan, M.R.C.S. For welfare service in Nyasaland.

Kaisar-i-Hind Gold Medal

Perakathu Verghese Benjamin, Medical Superintendent, Union Mission Tuberculosis Sanatorium, Arogyavaram, and Technical Adviser to the Tuberculosis Association of India, Chittoor District, Madras.

Norman Macpherson, F.R.C.S. Surgeon, United Missions Hospital, Vellore, and lately i/c Afghan Mission Hospital, Peshawar.

Henry Edward Shortt, C.I.E., M.D., D.Sc. Col., I.M.S., Inspector-General of Civil Hospitals, Shillong, Assam.

Frank Tomisman Simpson, *M.C.*, M.B. Lieut.-Col., lately Medical Officer in the Coalfields, Bihar.

(To be concluded)

Correspondence

Prisoner-of-War Mentality

SIR,—Because there is delay in the arrival here of my *Journals* I have only recently read the correspondence on the prisoner-of-war mentality. I am amazed to find in Dr. Harkness's letter of April 22, 1944, the statement that "*the very large majority of our returned prisoners-of-war will be problems for their lifetime.*" (My italics.) It has been my privilege for the last three and a half years to administer the medical affairs of large groups of wounded and disabled prisoners. These groups consisted of some of the worst of our *grands blessés*—the totally blind, the double or single amputated, the extensively burned, the paralysed, and the major orthopaedic cases. Nearly all of these patients had known several years of captivity; nearly all of them had suffered hard disappointment when the first attempt at repatriation broke down at Rouen in October, 1941, and they returned to the prison camps instead of going home.

No one realizes more acutely than I do the pressing psychological problems which in certain cases have resulted from years of enforced idleness, of monotony, and of physical suffering and disablement. If any group of prisoners-of-war was likely to present psychological problems it was the kind of group with which I had to deal. Nevertheless I most emphatically deny that anything approaching a majority of prisoners will be "*problems for their lifetime.*" Rather would I say that the majority of these men have gained in tolerance, understanding, patience, forbearance, and courage. They have acquired a bigger concept of comradeship and of community life. They have more fully recognized the need for the individual to pull his weight in the interest of the group. If a man was disabled it became a matter of pride to him to be one of the "muckers"—the man who was ready to "muck in," to lend a hand, and accept his responsibilities. The average prisoner has demonstrated a high standard of adaptability, and will do so again when he returns home to a post-war world. He will be out of touch in much the same way as any normal man who has been abroad during the changes of the last few years. He will need time to pick up the threads of his life again, but he will not have a peculiar mentality. I have shown Dr. Harkness's letter to several of the men here—cheerful, average, level-headed individuals. They expressed themselves as follows: "Afraid he doesn't altogether know what he is talking about: a few special cases, yes! but not the very large majority."

By all means let us arrange for physical and mental rehabilitation where it is needed. By all means let us make some allowances for the fact that the average prisoner-of-war is not adjusted to the change of the last five years. But do not let us discuss the majority as if they were psychopathological problems. Above all, let us avoid discussing their "mentality" in the lay press. If Dr. Harkness's statement were true, and if we were to follow his recommendation for wide publicity, "the powerful advocacy of the Press" would hardly be sound psychological treatment for the prisoner; nor would it encourage employers to select him as a worker. It is my belief that the responsible Departments of the Government will make a true assessment of the problem, and will provide adequate means of rehabilitation. It will not be difficult for them to obtain accurate information based on actual observation by medical officers and by laymen, who have been with the prisoners over long periods and under changing circumstances.

I have lived with prisoners-of-war of all ranks, of all the Services, from all the European fronts. On their behalf I resent any implication that they are below average in the qualities of balance, steadiness, patience, perseverance, tolerance, or good humour. The average prisoner is not a "problem" to himself, his companions, or his future employer. Surely Dr. Harkness takes a very pessimistic view of the mental and moral stamina of our race.—I am, etc.,

D. L. CHARTERS,
Major, R.A.M.C. (P.O.W. 23911).

Stalag IX B.

Underwater Blast Injuries of the Abdomen

SIR,—The article "Underwater Blast Injuries of the Abdomen" by Major T. Moore in your issue of Nov. 11 is of great interest to personnel of general hospitals receiving survivors of sea battles. Considerable numbers of such cases were seen as the result of naval incidents in the Eastern Mediterranean, particularly the battles of Matapan and evacuations from Greece and Crete. The surgeons concerned no doubt came to similar conclusions and obtained comparable results to those of Major Moore, but there appears, even with Major Moore, to be some doubt as to the exact mechanism of the causative agent within the abdomen.

The release of pressure from a dense to a less dense medium is transformed into the effects of a blow, which is easily understood in its possible effect on the walls of a submarine or the soft walls of an abdomen. This would surely be increased at depth, and lessened on the surface where the vastness and compressibility of the adjoining lesser medium of the air would take up and absorb the blow effect. This would explain why the floating body is less affected than the vertical. If this were the only explanation one would expect to see similar changes in the abdomen of a person exposed to blast on dry land, making due allowance for the density of air as against that of water—i.e., at a much smaller distance from the explosion the initial blow would be as severe. This is leaving out of account any other injuries sustained by the immediate negative pressure of blast effects in air.

It is thought that all the effects as described by Major Moore could be caused by the application of a sudden pressure blow to the soft and relaxed perineum as well as to the abdomen. In either case this by conduction would be transmitted along a gas- or fluid-containing hollow viscus like the colon, with disruptive effects at the first area of resistance—a mass of faeces, the bend at the splenic flexure, etc. If the blow is less severe but nevertheless sudden enough to be exerted before external reflex resistance could be established the effect might be transmitted further along and around bends of the large intestine, but would be multiplied and become disruptive in its effect on coming to a dead end or by being transmitted into a lesser lumen as at the ileocaecal junction and at further bends along the course of the ileum.

A simile could be found in the hydraulic brake system of a motor car, in which a gentle pressure on the foot pedal transmits through the master cylinder sufficient energy in the small-bore brake tubes to operate strong and powerful brakes. Anyone knows how a sudden jab at the brake pedal in this system is transmitted into a terrific multiplication of energy at the brake end of these small-bore tubes, sufficient to lock the brakes or even to disrupt the joints.

The man with a "Mae West" applied under his armpits has difficulty in assuming any position other than the vertical. He flexes his lower limbs in order to prevent spinning and to help to get away from the centre of the fray or the sinking ship. He backs away, his abdomen and his perineum are exposed and relaxed. The man floating on his back has his legs extended, the perineum is retracted, covered, and protected, and his abdomen is close to or exposed to the more expansile medium of the air. If a "Mae West" could be so adjusted that one could lie extended along it many casualties of the nature described might be avoided.

If the suggested explanation of the mechanism of this injury is correct it should not be difficult to introduce a drill in order that one should know what to do if ever unlucky enough to be a bit of flotsam in the midst of a naval engagement with underwater explosions going on around one. The views of others would be interesting and I feel sure would not be unwelcome to Major Moore.—I am, etc.,

J. MELVIN,
Colonel.

The Hospital Physicist in the Services

SIR,—The attention of bodies responsible for radiological appointments has, on a former occasion, been drawn to the need to ensure that men serving with H.M. Forces do not stand at any disadvantage as compared with their colleagues at home.

We are now requested to draw attention to the position of physicists at present serving with the Forces who may soon be returning to civilian life, and some of whom may very well, we trust, become interested in the possibilities of hospital physics as a career. During the war a number of hospital physicist appointments have been made from among men who, for various reasons, have been directed to work in civilian hospitals, and who have thereby become experienced in the work and have acquired the "hospital outlook" which is so essential for proper co-operation with the radiologist. It would obviously be unfair if, by comparison, the man who has been serving in the Forces stood at any disadvantage, and we have reason to believe that the hospital physicists concerned are themselves anxious that this should not be the case.

It is therefore urged that hospital and radiological authorities should do everything possible to help the "return to normal" of physicists now in the Services, and to ensure that war service and lack of special experience are not a handicap in applications for physicist posts. In our opinion his probability of appointment should at least correspond to that which a physicist might have expected if he had remained at home and not joined the Services, and, if necessary, allowances should be made for him to undertake the concentrated training required to bring his knowledge up to date and up to standard.

The importance of the physicist in radiological departments is now generally recognized, not least by the radiologist, and it is felt that some acknowledgment of this can be made by radiological bodies in attempting to secure a fair deal for their physicist colleagues who have been on service.—We are, etc.,

L. H. GRAY,
HUGH DAVIES,
Hon. Secretaries, British Institute of Radiology.

J. F. BROMLEY,
Hon. Secretary, Faculty of Radiologists.

Faculty of Radiologists, W.C.2.

The G.M.C. Elections Decision

SIR,—In the debate on the Address (Hansard, Dec. 14) the Deputy Prime Minister deprecated the holding at the present time of the election of 39 members of the General Medical Council, 7 of whom only are elected by medical practitioners, on the grounds that "the medical electorate numbers somewhere about 65,000. The strain on the medical profession at the present time is immense. The fact is that people do not know where a large proportion of those 65,000 members are. A large proportion of them is over-seas. A great many of the other doctors have been moved about the country according to the exigencies of war." Dr. Russell Thomas very usefully directed the attention of the House to the Deputy Prime Minister's argument against present changes affecting doctors and declared that "the Rt. Hon. Gentleman on behalf of the Government has made it perfectly clear that the medical profession cannot be expected to come to any decision on any matter at the present time." The election of 7 members of the General Medical Council is surely a less important matter than the decision of the conditions of future medical practice in this country. I submit, Sir, that the Deputy Prime Minister has shown a more realistic appreciation of the facts as they are than the Prime Minister and the Government, who propose to introduce legislation revolutionizing medical practice in defiance of the clear undertaking given by the Prime Minister himself in the House on Oct. 13, 1943, in the following explicit terms: "There is no question of far-reaching changes of a controversial character being made by the present Government unless they are proved indispensable to the war. Another Government might take a different view, but not this one. I certainly could not take the responsibility of making far-reaching controversial changes which I am not convinced are directly needed for the war effort, without a Parliament refreshed by contact with the electorate."—I am, etc.,

House of Commons, S.W.1. E. GRAHAM-LITTLE.

Time of Ovulation

SIR,—I thank Prof. W. J. Hamilton for his interesting comments (Dec. 9, p. 768) on my observations concerning your annotation on the time of ovulation. The matters raised need further consideration. References have already been given to the works cited below and are not repeated in this communication.

1. Prof. Hamilton claims that had pregnancy not supervened in the Davies-Harding case the present cycle would have been 24 days (compared with the previous regular 28-day cycles). He bases this opinion on my report that the endometrium on the 20th day was as far advanced in the secretory phase as that on the 24th or 25th day in other patients with 28-day cycles, who probably ovulated about the 14th day, and on the findings of Rock and Hertig, who estimate the interval that they would expect to elapse before the next catamenia by the stage reached by the endometrium in their specimens. But Rock and Hertig themselves admit that this estimated time is "uncertain" and "imponderable." I had previously considered this deduction (in the Davies-Harding case), but I rejected it because there is no conclusive evidence that the duration of activity of the corpus luteum (of menstruation) is rigidly constant. To make matters plain, I believe the available evidence indicates that, while the secretory phase will be *attained* early in the cycle if ovulation is early, this phase will be *maintained* so long as the corpus luteum remains active; the next menses will not ensue until this body ceases its activity, and there is no certain means of foretelling the time of this latter event.

2. Prof. Hamilton questions the conclusions drawn from their own evidence by Miller, Engel, and Reimann, but, while quoting the paper recently published by Rock and Hertig (*Amer. J. Obstet. Gynec.*, 1944, **47**, 343) in connexion with the endometrial structure, he ignores the important fact that in the same paper these authors estimate from a study of 3 unfertilized and 11 fertilized ova that the interval between ovulation and the next expected menses in these cases ranged from 11.5 to 17 days. In the case of the fertilized specimens these figures were obtained by adding the estimated age of each embryo to the estimated interval between operation and the next catamenia as judged from the condition of the endometrium (although, as stated above, they admit that this last estimation is "uncertain" and "imponderable"). When they computed the lengths of the estimated post-ovulatory phase in terms of "percentiles" of the estimated lengths of the menstrual cycles they found that the average of these percentages did not deviate from that calculated, by using the theoretical figure of 14 days for ovulation time, sufficiently to interfere with the indication that ovulation occurs about 14 days before the expected onset of the next period. But these results relate to the average for the series of 11 cases; it appears to me that they cannot be safely applied to individual cases, and I believe they mean nothing more nor less than that ovulation most frequently occurs round about 14 days before the next menses, but that it may occur outside this limit, as is indeed revealed by the figures in their individual cases.

3. When all the evidence in the literature (including the recovery of tubal ova and young intra-uterine embryo) is weighed up I maintain that we can infer, as I stated in my previous letter, that while ovulation commonly occurs round about 14 days before the expected onset of the next menses it may occur outside these limits. I anticipate that, as more and more cases are scientifically investigated (preferably by the methods which do not interrupt the normal cycle), the range in ovulation time will be found to extend considerably beyond the narrow limits of 14 ± 1 days before the next period. Prof. Hamilton's discovery of another two ova which indicate that ovulation occurred within the narrow limits does not materially affect the argument, since no one denies that this is the optimum time for hunting for ova in a series of women; obviously if the search were confined to these limits no ova would ever be found outside them.—I am, etc.,

Anatomy Department, University of Sheffield. FRANCIS DAVIES.

Skin Sterilization by Colourless Flavine

SIR,—Concerning our paper on this subject, that appeared in your issue of Aug. 12, 1944, Mr. Kearney wrote you a letter a few weeks later suggesting commercial spirit in place of rectified spirit to reduce the cost. We therefore prepared our solution thus modified and subjected it to further tests, the results of which show that its efficacy is not lessened by the substitution.—We are, etc.,

VICTOR BONNEY.
H. SANDEMAN ALLEN.

Treatment of Varicose Ulcer and Eczema

SIR,—The introduction of elastic adhesive bandages has greatly improved the treatment and ultimate prognosis of varicose ulcers. There are, however, certain difficulties and disadvantages:

(1) A number of patients are sensitive to the chemical constituent of the adhesive surface which causes extensive local and general dermatitis, and very soon the patient decides to bear the suffering from the ulcer rather than the irritation and pain of dermatitis resulting from the treatment. Application of these adhesive bandages is particularly hazardous in cases of varicose ulcer where some degree of eczema is coexistent with the ulcer. Some 20% cases fall in this category. To meet this difficulty the manufacturers have produced a half-spread adhesive bandage where the adhesive surface comes in contact with the foot only, the non-adhesive half of the bandage being in direct contact with the leg. If the sensitivity of the patient's skin is localized to the ulcer area this device meets the situation. But very often one comes across patients with varicose ulcers, possessing a high degree of sensitiveness to this adhesive material, and in such cases the result is painful dermatitis.

(2) Another very serious though fortunately very rare complication of this form of occlusive dressing is sudden and alarming haemorrhage from the large area of granulating surface of the ulcer at a healing stage. A large quantity of blood may accumulate underneath the bandage and may not be obvious to the patient for some time. When it is, the patient may have great difficulty in removing the bandage promptly.

(3) There is great scarcity of these bandages at the present time. The modified treatment I suggest will result in considerable economy of material, more comfortable treatment, and avoidance of the risk of haemorrhage.

The promotion of healing of these ulcers depends on the elastic property of the bandage, which by compression of the varicose veins causes more prompt return of the venous blood and improved nutrition of the diseased part. The adhesive quality of the bandage is not an advantage but a disadvantage. For the last five years I have discarded the use of elastic adhesive bandages, and have treated 112 cases of varicose eczema and ulcer with 100% success by using elastic web bandage.

The ulcerated or eczematous surface is cleaned with soap and water and dried. Then it is painted with 2% aqueous solution of crystal violet. A generous quantity of a powder consisting of zinc. oxidi ʒii, calamini ʒii, kaolin ad ℥ii is sprinkled on the ulcer and a pad of gauze is applied and bandaged over with an ordinary bandage. The limb is then enclosed in a 2½-in. or 3-in. wide elastic web bandage in a spiral fashion from the base of the toes to below the knee, with light pressure over the ulcerated area and more tightly above. This procedure is repeated every morning. Before going to bed at night the patient removes the elastic web bandage. To be able to remove the bandage at night is greatly appreciated by patients. In a few days a clean hard crust is formed over the ulcer; whereas in the occlusive treatment with elastic adhesive bandage the accumulated discharge causes a very disagreeable odour. In cases of varicose eczema no dusting powder is used, unless a good deal of discharge is present, which is unusual. Otherwise the procedure is the same.—I am, etc.,

Burton-on-Trent. MANIK GHOSH.

Surgical Approach in the Obese

SIR,—I was recently asked to operate on an exceedingly obese young woman suffering from an acute appendix, her height being about 5 feet and her weight approximately 16 stone. It was realized from the first that she would probably be a bad case for surgery, as in all obese patients the approach to the abdomen is usually a difficult problem.

In order to overcome the thick mass of fat through which one had to operate, it was felt that a better approach could be obtained by adopting a horse-shoe incision to reflect a flap such as that used in cranial surgery, the flap in this case being the skin and fat down to the abdominal muscles. An incision was therefore made starting just above the mid-Poupart area curving outward and upwards to just above the umbilicus. From this incision was dissected upwards and inwards the whole mass of skin and fat, which on being swung inwards exposed a complete area of external oblique muscle ready for further steps. The rest of the operation was carried out by the usual gridiron method. During the period of the operation the flap was well protected by hot towels wrung out in saline.

The chief impression left by this procedure was the ease with which the essential parts of the operation area could be approached as compared with the meagre space one has when operating directly downwards through fat. While claiming no originality for the method, none of my colleagues or myself have seen any reference to this mode of approach, and it is felt that if such procedure is in use it should be given more prominence. It is an approach which could have many variations, and possibly in this case it might have been better to have turned a flap outward from the midline instead of inwards.

Whether this type of flap could not be used on huge fat limbs for a better approach is also another point which might be taken. In any case I feel that the procedure would answer many of the difficulties in the operative approach to the obese person.—I am, etc.,

Caernarvon. W. HILTON PARRY.

Smoking and Duodenal Ulcer

SIR,—If I may very shortly reply to Sir Adolphe Abrahams (Dec. 16, p. 798) I would like to say that the remark of my cynical friend about tobacco dividends is, of course, wholly untrue, and that in print it does not look as well as I thought on hearing it.

As regards smoking I emphasized the cigarette habit, and did not concern myself with pipe smoking, which was the general form of tobacco indulgence 40 to 50 years ago, when cigarette smoking and duodenal ulcer were both uncommon.

As to the present-day prevalence of duodenal ulcer among women an *x*-ray expert, even six or seven years ago, while he scoffed at the cigarette idea, agreed that he was seeing a number of cases of duodenal ulcer among women; and in a letter dated Dec. 7, 1944, a doctor wrote to me: "It was formerly very uncommon for women to suffer from these ulcers, but I have recently seen quite a lot—all heavy cigarette smokers."

As to the time taken for the development of a duodenal ulcer I would urge that it takes many a drop of water to wear away a stone and many a gill of gin to produce a cirrhotic liver. I wonder how many years it took for that type of cirrhotic liver to be accepted as due to gin.—I am, etc.,

Southwater. V. S. HODSON.

Certification for Extra Milk

SIR,—It may at this juncture be of interest to your readers to learn of this experience of mine. I have been in the habit of prescribing priority milk supplies under the heading I, II, etc., and the Food Registration Officer writes to say:

> "I have received several certificates issued by you bearing only the class number (I or II) and no indication of the category (a, b, c, etc.). . . . I must ask you to comply with the Ministry's instructions in this respect."

In the course of my reply I wrote:

> "You have my sympathy in this matter of the formal demands of the Ministry; but unfortunately the Ministry appears not to have realized fully the difficulty in which a doctor finds himself. You will no doubt remember that it was in response to representations by the medical profession that the Ministry agreed that the doctors need not give the diagnosis (name of the disease or disorder) in respect of which the patient was being given milk certificates; but it was very cleverly forgotten by our 'form-mongers' and 'red-tape people' at the Ministry that the other requirement—viz., that the class (I, II, III, etc.) together with the subheading denoted by a letter (a, b, c, d, etc.)—was equivalent to the diagnosis in most cases. For example, I a told the whole world that the case was one of tuberculosis; I d says plainly gastric or duodenal ulcer; I f, operation; I g again reveals the possibility of tuberculous disease; and I h one or other form of malignant disease. Class II may be analysed in the same manner.
>
> "Now, Sir, there are many people who object to anyone knowing of their physical disabilities; I have indeed at the present time three patients who have very strong objections on several counts that their doctor should reveal to anyone the nature of their maladies, and I need hardly remind you of the duty of the doctor in the matter of professional secrecy. So that whensoever I feel that I should be acting indiscreetly by doing otherwise I shall continue to issue certificates in the form which you say I must modify to be in keeping with the Ministry's demand. . . . I can only suggest

that in order to place yourself in a safe position you should send this letter to the Ministry of Food and possibly the Minister of Health for their further instructions; and in the meantime please allow the validity of my certificates so that the public I serve may not suffer."

I have not heard again from this functionary.—I am, etc.,

Acton, W.3. A. R. EATES.

Preamble to Post-war Food Education

SIR,—Mr. Le Gros Clark (Dec. 9, p. 763) must begin with foundations. It is not "a matter of changing views and practice of women in the kitchen," but, as Rowntree and Huxley have shown, of securing food of proper quality in the shops and money in housewives' pockets to buy it with.

When attempting to persuade a rural authority to compost its refuse in 1940 I learnt from the Director of Rothamsted (Sir John Russell) and from the Professor of Horticulture at Reading (Dr. Stoughton) that there was no sort of experimental evidence to show that food (either animal or vegetable) grown on chemically fertilized soil would maintain fertility in succeeding generations. It would, of course, sustain life and strength (though not necessarily health) and was therefore admissible in wartime to preserve an island race from starvation. But it cannot compare with the product of biological fertilization as a basis for the exuberant health we plan for the future (McCarrison, Howard, etc.).

Prof. Miller of the Royal Veterinary College has said that "scientific" feeding has produced a deterioration in the health of farm animals, that the 3,000-gallon cow often aborts and becomes barren, and that the 320-egg fowl too often develops leukaemia, tuberculosis, or fowl paralysis. How are we to know that the flesh of these animals will maintain the human race in health and fertility? Can we not demand experimental evidence to equal that of Orr, Wrench, and the aforementioned authorities, before the chemical industry is allowed completely to dominate food production?—I am, etc.,

Caernarvon. GRIFFITH EVANS.

Medical Reciprocity with France?

SIR,—I venture to suggest that it would be a friendly if not actually a sound diplomatic gesture if the G.M.C. would admit to the *Medical Register* doctors who are in possession of a French degree. As it is, I know of at least one medical man who is actually a British subject and who is M.D.Paris and is disqualified here. He is not even allowed to take the final professional examination. There is, or was, reciprocity between this country and Italy. Is there any very good reason, therefore, why there should not be the same reciprocity with regard to France, especially in the case of those who are British subjects and who hail from one of our possessions?—I am, etc.,

Edinburgh. JAMES BURNET.

*** This is a matter for the Privy Council under Section 17 of the Medical Act, 1886.—ED., *B.M.J.*

Breathing and Coronary Circulation

SIR,—The death rate from angina pectoris and coronary artery thrombosis has rapidly risen in the last 30 years. In 1911–21 52 per million died from these complaints, in 1930 303 per million, and in 1940 967 per million. A patient aged 59 recently came to be examined because he had noticed so many people died suddenly, especially men. Acquaintances of mine who have died suddenly include a well-known provincial cardiologist from a coronary thrombosis, a Naval officer aged 53 was found unconscious suffering from a coronary thrombosis, and three doctors aged 55, 62, and 45.

Can nothing be done to check this increased mortality? Certainly no drugs or dieting will help. Is there any physical method that would help? It is possible that sustained increase of well-oxygenated blood to the heart would help. The problem is to produce this condition; the left ventricle, elastic arteries, and gravity help the outflow to the tissues; but the return of the blood to the heart is retarded by gravity and the lack of elasticity and poor valves in the veins; to the rescue comes the suction action of the thorax during inspiration. Unfortunately in so many men the thorax scarcely moves during inspiration, but it is otherwise in most women. If physical means will help, the exercises to be given are:

(1) To put most of the body weight on the balls of the toes when standing and also when sitting. This stance tones up the muscles of the feet, the legs, the thighs, and the abdominal muscles, and thus helps veins and lessens the action of gravity.

(2) To see that the thorax moves sufficiently when breathing This is done by keeping the shoulders tightly back and slightly down and holding them steady there during inspiration and expiration. To keep the shoulders tightly back is done with least effort by getting the pull in the back just below the axillae.

(3) In addition to the above, deep thoracic breathing should be undertaken, say, twice a day, and the range of movement should be checked in front of a mirror to be sure the thorax is really moving.

Naturally this idea and its results cannot be proved, but it is common sense to ensure plenty of blood to the arteries and muscles of the heart if the heart is to keep free from disease. All, especially men who fear that these complaints may be their weakness, would do well to follow these simple suggestions of breathing and stance during the day.—I am, etc.,

Ealing, W.5. R. H. DIXON.

Colonial Medical Services

SIR,—You have recently published many letters criticizing the various Colonial Services and their organization which would tend to make the reader at home rather ashamed of those services. Those letters, too, may well have a worse effect—that of preventing the young doctor at home from applying for appointments abroad. It is well to realize that any service, especially a medical one, is open to criticisms, and often is unable to reply completely to them.

The majority of Colonial Medical Services have fewer than fifty British doctors. This staff is responsible for administration, surgical, medical, and public health work throughout their own territory. That territory often comprises a few busy crowded towns, but in the main is African bush inhabited by different tribes speaking different languages and having different customs. The doctor should be able to adjust himself so that he can institute the essential medical services under many and varied conditions. Only too often is he hampered in his work, not by red tape and officialdom, but by the ignorance and non-cooperative attitude of the native. Superstition and magic still play their part, and modern medicine, no matter how high may be one's ideals or how energetic one's enthusiasm or how capable one may be, is still an uphill job. This is only too true in the towns, where one would expect a little enlightenment and co-operation.

During the last few years of war those medical services have had an even more difficult task. The civilian doctors have been recruited as medical officers in the various native Army Corps that have done such fine work for the Allies. The remaining civilian doctors, short of staff, short of drugs, and with little leave, and as often as not separated from their wives and families for prolonged periods, have not only maintained these essential services but in many instances have improved them. They have been faced with new problems such as yellow fever; they have had to man base hospitals and do military work of all kinds in addition to their own civilian job.

These times of stress have naturally brought to light some of the age-old grumbles. To shout these from the house-tops and to allow letters to be published decrying our Colonial Services is not fair to those who have done the job. There are doubtless many causes of complaint which could be settled internally, and will be settled after the war. As a member of a similar service for the last twelve years I beg to make the following suggestions:

1. No one should come out and expect to start as a specialist. A sound general knowledge of the difficulties in all parts of the territory is necessary. Every doctor, no matter how specially qualified, should do his turn of administration, public health, and so forth.
2. The administrators must be men of personality, who know the country. Personality and the power of leadership are essential qualities for a director of medical services. Without these even the most ideal man, with the most generally accepted and ideal policy, will not go far.
3. Regular facilities for study leave must be organized and granted to all.
4. Promotion on merit and not on mere seniority should be the rule. Merit includes suitability for the post.

5. Opportunities for members of the medical service to travel and see how other Colonial Medical Services work should be provided regularly.

6. Much medical work is hampered by lack of funds. Grants from the home Government should be made more frequently to enable the medical services to be more effective.

All medical services among African communities need not only first-class British doctors but also first-class British nursing sisters to train and supervise the nurses in native wards. These are not always forthcoming, but they are as essential as the doctors. I have had the opportunity of seeing something of the medical services in the Sudan, Uganda, Kenya, and of meeting some of the medical officers from Nigeria, as well as of seeing something of the medical services in the Belgian Congo and French Equatorial Africa. I have been amazed that so few doctors have managed to achieve so much under such difficult circumstances. They might have achieved more if all their grievances had been attended to, or if they were given more opportunity by the natives themselves. We must look at these services in their true perspective. In my opinion they have achieved something of which British medicine may well be proud.—I am, etc.,

"CREDITOR."

The Young Married Doctor

SIR,—I was interested to read "Married Doctor's" letter (Dec. 23, p. 835). The lack of accommodation for married men in hospitals, where the appointments are not for six months or a year but are so-called permanent posts, is a source of much distress and discontent, which is inevitably reflected in the quality of the service. This is bound to be less wholehearted than would be given by the same men in happier circumstances. Those responsible for hospital administration should realize that if they alter their attitude to this question their hospitals would gain not only by the increased efficiency which results from good working conditions but also by the retention in their service of men of high qualifications and attainments, who are forced at present to take up other branches of medicine if they wish to marry and have a normal life.

Industrial psychologists teach that a high labour turnover is indicative of an unhealthy organization; this is true of hospitals as well as of factories. It is particularly true when the turnover occurs, as in this case, among responsible officials, so that there is a lack of that continuity of leadership which makes for happy and efficient teamwork. More especially is it true where patients are suffering from illness requiring long-term stay in hospital, when the advantages of a reasonably stable staff are incalculable.

But the provision of suitable married quarters is only one step on the way. Most doctors look back with real affection to their days as house-officers, working and living as the members of a closely knit community. Few would care to lead such an existence for the rest of their professional lives, yet that is what even a senior resident medical officer is expected to do at present. Sometimes the quarters and furnishings are relatively good, but it is seldom possible for him to make a real home for himself. He is usually completely dependent for food and for cooking facilities on the main or ward kitchen. He has no garden where he can sit or work in the fresh air with any degree of privacy. He is unable to have friends to visit him with the freedom which is desirable, especially when, as is often the case, he cannot leave hospital for days on end. There may be excellent reasons for a man not marrying, but there can be none to justify his being prevented from having as rich and full a life as possible. I can speak from personal experience of the recreative effect of an hour or two in a colleague's home, where one may talk "shop," but where one does escape for a little from the "institution" atmosphere, and yet be on hand if required.

There is a strong case for the provision of proper accommodation for resident medical officers holding other than house appointments. It does not necessarily follow that we think that such accommodation should be a charge falling wholly on the hospital authorities. Many would be glad to pay a reasonable rent in return for the opportunity to live their own lives when not actually at work—surely one of the rights of every individual.

This problem is closely linked with another, also the subject of recent correspondence—namely, the pay of medical officers, especially in mental hospitals. The solution of both is largely dependent on the governing bodies recognizing that the day of the underpaid, badly housed, mediocre, often intemperate hack has passed for ever, and that there are many keen, well-qualified men anxious to give of their best in hospital work if they are given a reasonable livelihood and the chance of a normal home life.—I am, etc.,

"B.1."

Medical Demobilization

SIR,—The *Journal* for Nov. 4 has just reached me [Dec. 12] in the field in Italy. I would like to comment on the statement concerning the special position of medical officers in the Government's proposals for demobilization at the end of the European war (p. 605).

I note that "recommendations for transfer of medical officers under Class B will be made by the Central Medical War Committee after consideration of applications submitted through the Local Medical War Committees." This means that for all practical purposes medical officers qualified since September, 1939, who, because they were in house appointments or were only assistants in general practice, were called up first will not have a chance of release under the Class B scheme, the reason for this being, quite simply, that as they have no practice and do not in the main belong to any local Division of the B.M.A., no Local Medical War Committee is going to put up a request for their release under Class B. They themselves do not, at least from the article quoted, appear to have any other hope of early release under the B class except through the local committee's application. Thus the fact has been completely ignored that they, more than any older officer, will want to start as soon as possible either studying for their postgraduate degree (which their E.M.S. colleague has now collected in comfortable civil life) or, alternatively, to start in general practice.

I should have thought that the Central Medical War Committee could have initiated some applications itself, in the case of younger medical officers without local associations or practices, and at the same time recruited some of the E.M.S. officers, who have so far been deferred, to take their places. These, along with those Category C men who were admittedly not fit for war but who would be quite suitable for line-of-communication duty in an Army of Occupation, and the annual number of newly qualified doctors, should be ample to release those medical officers who have served long enough to qualify under the Class B scheme or who want release under Class B.

As the matter stands now the younger medical officer, if he has to compete with the older man with a colleague in his practice to put his case up to the Local Medical War Committee, has no chance at all, and looks like stopping in the Service—that is, first in and last out.—I am, etc.,

In the Field, Italy. "SERVING OFFICER."

Débridement et Épluchage

SIR,—Mr. d'Offay is wrong when he says that *débridement* has nothing to do with debris. The first five letters are the same and are pronounced in the same way, and hence it is easy to transfer the idea of the one to the other. Etymologically, of course, he is right: *débridement* is from *débrider* and *débris* from the obsolescent verb *débriser*, as can be found out by looking up a dictionary. But something more important than etymological purities is involved. Surgery wrung a new principle of healing out of the experiences of the last war, the discovery that it is easier to get rid of organisms from wounds by robbing them of food than by bombarding them with protoplasmic poisons, and in so doing anticipated the principle of modern chemotherapy by twenty years. A surgical principle of such importance is worthy of a special descriptive term. The term "excision" will not do, as it gives no indication of what is excised; in fact, the principle of débridement, or desloughing, can often be achieved in face and scalp wounds without any excision at all, as, owing to the good blood supply, there is no tissue debris or potential slough to excise. "Wound toilet" is likewise, and for similar reasons, inadequate. Anyone who objects to the terms "débridement" or "desloughing" must find in their place an equally vivid descriptive term.—I am, etc.,

London, W.1. DAVID H. PATEY.

Obituary

T. N. KELYNACK, M.D., M.R.C.P.

We regret to announce that Dr. Theo. N. Kelynack died on Dec. 23 at his home at Harpenden, aged 78. Dr. Kelynack edited the *British Journal of Tuberculosis* for 27 years, the *British Journal of Inebriety* for 32 years, and *The Child* for 17 years. Among the many posts he had held was that of physician to the Mount Vernon Hospital before it moved from Hampstead to Northwood, and he continued his active connexion with it until it ceased to be a hospital for diseases of the chest, when the governing body appointed him honorary consulting physician.

Theophilus Nicholas Kelynack, son of the Rev. N. Kelynack, was born at Wells, Somerset, on June 26, 1866. From University College School, London, he went to study medicine at Owens College, Manchester, and graduated M.B., Ch.B. with distinction at the Victoria University in 1889. He was awarded the gold medal in 1893 for his M.D. thesis on the pathology of the vermiform appendix, and he took the M.R.C.P. two years later, after serving as house-physician, pathologist, and medical registrar at the Manchester Royal Infirmary. Before coming to London he had been demonstrator and assistant lecturer in pathology and assistant to the professor of medicine at Owens College.

Dr. Kelynack had a deep feeling of social responsibility, and in the early years of this century began to write on the alcohol problem. He compiled many health manuals, and for a number of years acted as joint honorary secretary of the Royal Institute of Public Health; he was also honorary secretary of the Society for the Study of Inebriety, whose journal he edited from 1903 to 1935. In the early years of his appointment at Mount Vernon he wrote on the sanatorium treatment of consumption and edited a book, *Tuberculosis in Infancy and Childhood*, by various writers (1908); he also edited *Defective Children* and *The Drink Problem of To-day in its Medico-Sociological Aspects*, of which a second edition appeared in 1916, and *Human Derelicts*. Other publications associated with his name were the *Tuberculosis Year Book and Sanatoria Annual* (1913); the *Year Book of Open-Air Schools and Children's Sanatoria* (1914), and the *Child Welfare Annual* (1916). Dr. Kelynack was also visiting physician to the Harpenden Sanatorium for Children and medical adviser to the Shaftesbury Society and the National Children's Home and Orphanage. In 1919 he was appointed a J.P. for the County of London. His wife, the late Dr. Violet Kelynack, was medical secretary of the Medical Women's Federation, and his daughter, Dr. Agnes Kelynack, is now assistant secretary of the B.M.A., after being senior medical officer for civil defence under the Essex County Council.

CHARLES LEONARD ISAAC, M.B.CAMB., F.R.C.S.ED.

Colonel Charles Leonard Isaac died at the age of 67 at Swansea, his native town, on Nov. 6, 1944, after a brief illness. He was the son of a well-known solicitor, and graduated M.B., B.Ch. at Cambridge in 1904. Soon afterwards he started in practice in Swansea, and rapidly attained a place on the honorary staff of the Swansea General Hospital and was senior surgeon there from 1919; he became very well known over a large part of South Wales. In the last war he entered a new field of activity and served with distinction in the R.A.M.C. in France. Military surgery and the Army life suited him, and after the war he took a most active part in Territorial Army affairs, ultimately serving as A.D.M.S. in the Western Command. The age limit enforced his retirement from active military life shortly before the present war. During his active period he had had the distinction of being Honorary Surgeon to the King, and he had also been a deputy-lieutenant of the County of Glamorgan.

Isaac was an active member of the B.M.A. and had been chairman of the Swansea Division. In the years between the wars he took a very full part in the work of the British Legion and the welfare of ex-Servicemen. Medical and hospital politics did not attract him, though his military record affords evidence of administrative capacity. Popularity came to him unsought; it was impossible to be gloomy when Col. Isaac was present, and no circumstances of war or blitz appeared to perturb him. He was witty and very quick in response, and his friendly bantering chaff and good-natured humour were a source of joy to all who came into his circle. His quickness of mind was reflected in his work as a surgeon; he would decide rapidly whether to operate or to refrain, and when operating his technique was rapid and dexterous, a pleasure for his co-workers to see and a matter of legitimate pride for himself. Isaac enjoyed the social life and was a well-known figure in the life of his locality. He was particularly prominent as a medical witness in the courts and had achieved a merited reputation as a helpful and unbiased guide in cases of litigation. A notable tribute to his work as a witness was paid from the Bench and the Bar at the county court after his death.

As a personal friend he was generous, hospitable, and unchanging; he disliked quarrels or bickering, though quite able to assert himself effectively when occasion arose. His death deprives Swansea of a surgeon of distinction—a man well beloved by his colleagues, by a wide circle of friends in many spheres of life, and by many grateful patients. He is survived by his widow, a son now serving in India in the Royal Artillery, and a daughter serving in the W.R.N.S.

A. F. S.

The Services

Col. J. W. Vanreenen, O.B.E., I.M.S., V.H.S., has been appointed Honorary Physician to the King in succession to Col. R. V. Martin, C.I.E., I.M.S. (ret.).

Temp. Surg. Lieut. H. R. Gray, R.N.V.R., has been mentioned in dispatches. This name appears in a list of awards for gallantry, skill, determination, and undaunted devotion to duty during the landing of Allied Forces on the coast of Normandy.

Surg. Lieut. J. F. Hanratty, R.N.V.R., and Temp. Surg. Lieut. L. A. H. Willson, R.N.V.R., have been mentioned in dispatches for good work in damage control and the care of the wounded.

Lieut.-Col. D. D. Logan, D.S.O., Lanarkshire Home Guard, has been appointed O.B.E. (Military Division) in recognition of meritorious service in the Home Guard.

The *London Gazette* has announced the following appointments and awards in recognition of gallant and distinguished services in Italy:

C.B. (Military Division).—Brig. (Temp.) R. W. Galloway, C.B.E., D.S.O., late R.A.M.C.

C.B.E. (Military Division).—Col. (Temp.) J. B. S. Guy, O.B.E., T.D., R.A.M.C.

O.B.E. (Military Division).—Cols. (Temp.) G. Anderton, W. J. F. Craig, and J. C. Gilroy; Lieut.-Cols. D. McVicker, M.C., G. B. Mitchell-Heggs; Majors (Temp. Lieut.-Cols.) F. H. Bentley, H. D. Chalke, F. G. Holman, J. G. Jamieson, F. R. Langmaid, A. J. Pitkeathley, J. K. Slater, and D. T. Swift, R.A.M.C.

M.B.E. (Military Division).—Major (Acting Lieut.-Col.) C. D. Preston; Capts. (Temp. Majors) J. A. Ross, R. A. Tennent, R. J. Toleman, B. McN. Truscott, R. I. Wilson, H. J. Bell, H. W. Burge, J. M. P. Clark, G. J. Cunningham, W. Davidson, D. J. Davies, F. C. Heatley, J. N. Macartney, I. A. MacDougall, W. L. Ogle, A. Orlek; Capts. A. P. R. Borrowman, M. C. H. Kingdon, F. E. Pitt-Payne, R. H. R. Renwick, R.A.M.C., Capt. M. G. Pendharker, I.A.M.C.

D.S.O.—Major (Temp. Lieut.-Col.) P. J. Richards, O.B.E., R.A.M.C.

M.C.—Capt. (Temp. Major) R. A. Hooper; Capts. J. Braham, A. M. Glaser, O. D. Morris, L. G. Morrison, and D. F. O'Neill, R.A.M.C.

Capt. (Temp. Major) F. J. G. Slater, Capts. T. G. Cameron, J. T. A. Lloyd, A. N. MacPhail, H. D. Moore, and J. A. Perpoli, R.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in N.W. Europe.

Capts. R. D. Barron, E. E. Miller, M.M., and W. F. MacKenzie, R.C.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in the field.

CASUALTIES IN THE MEDICAL SERVICES

Died in Burma.—Lieut.-Col. John Dennis Francis Armstrong, R.A.M.C.

Died on service.—Fl. Lieut. Ivor Mazure, R.A.F.V.R.

DEATHS IN THE SERVICES

Lieut.-Col. SYDNEY NUTTALL HAYES, O.B.E., died suddenly on Dec. [illegible] at Lahore, India, aged 53. He was educated at the Middlesex Hospital and took the M.R.C.S. and L.R.C.P. in 1918. In 1921 he passed the F.R.C.S.Eng., and the F.R.C.O.G. in 1934. Before qualifying in medicine he served for two years during the 1914–18

COLLEGE OF MEDICINE LIBRARY C. U.

war in the Royal Field Artillery Territorial Force. In 1918 he held a temporary commission as captain in the I.M.S., and in 1921 obtained a permanent commission. Later he specialized in gynaecology and obstetrics and obtained the professorship in these subjects at the King Edward Medical College at Lahore. He published papers on the sterilization of dressings and on the operative treatment of vesico-urethral and vesico-vaginal fistulae—distressing conditions seen very commonly in India on account of the backwardness of midwifery. Col. Hayes's early death at the height of his powers and usefulness is a serious loss to his specialty in India.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

Arthur Charles Douglas Firth, M.D., F.R.C.P., senior physician to King's College Hospital, London, has been elected into a supernumerary Fellowship at Trinity Hall.

At a Congregation held on Dec. 16 the degree of M.D. was conferred by proxy on P. L. Mollison.

The following candidates have been approved:

FINAL M.B.—*Part I. Surgery, Midwifery, and Gynaecology:* D. G. Abrahams, R. C. Allison, E. L. Arnold, A. C. Arthur, D. A. Bailey, D. A. N. Barran, D. V. Bates, A. D. Beard, R. Bellamy, J. P. M. Bensted, P. F. Boreham, A. R. C. Butson, R. E. Church, H. C. Churchill-Davidson, I. F. J. Churchill-Davidson, J. M. Cliff, N. K. Connolly, J. Crichton, W. P. Dallas Ross, N. N. Davies, I. M. P. Dawson, A. G. Dingley, N. K. Dryden, A. L. T. Easton, T. A. Evershed, W. S. R. Fenton, J. W. B. Forshaw, S. G. A. Forsyth, T. C. Gibson, R. N. Grabowsky-Atherstone, R. A. Green, E. Halász, R. J. Harrison, P. H. Hewitt, W. A. A. Hodges, R. Hyde, P. M. Jeavons, P. B. Kunkler, J. B. Lawson, C. B. McKerrow, H. B. Mallows, P. R. A. May, J. B. Metcalfe, C. M. Monro, W. J. Naunton, G. R. E. Naylor, K. M. Nuttall, C. J. H. Paget, T. C. L. Parry, B. W. Pay, R. F. Payne, V. R. Pickles, J. R. H Pinkerton, D. A. Pond, D. A. Pyke, R. Randell, J. O. Robinson, J. A. Rycroft, G. H. Seale, D. N. Seaton, D. W. S. Sheldon, J. C. Sloper, J. R. Smythies, R. E. B. Spencer, R. H. Thomlinson, M. G. Thorne, O. L. Wades, P. H. Walker, R. V. Walley, J. M. Walshe, W. R. Wardill, W. Waugh, J. A. Waycott, E. J. M. Weaver, J. E. M. Whitehead, D. Wilson, R. B. Wilson, J. H. F. Wood, S. P. Wrightson. *Women:* I. M. S. Chappel, C. E. Cooper, M. E. P. Hele, J. E. Keilin, M. M. Mason, M. C. Myddelton, L. A. Norris, N. J. Pease, H. M. Russell, C. N. Smith, J. Whitham. *Part II. Principles and Practice of Physic, Pathology, and Pharmacology:* T. B. Anderson, J. D. Andrew, C. G. Attenborough, D. V. Bates, H. H. E. Batten, T. C. Beard, W. M. Bennett, J. H. E. Bergin, I. J. Carré, W. R. Cole, G. N. Cooke, P. B. S. Cooper, J. M. Davis, C. H. de Boer, C. D. Drew, J. M. Drew, E. D. Dyson, H. L English, J. J. Fleminger, T. P. S. Frew, S. A. M. Garibian, H. M. Giles, J. S. R. Golding, M. L. Graeme, P. F. Haggart, R. J. Harrison, G. Hartridge, F. G. J. Hayhoe, P. R. Headley, I. S. Hodgson-Jones, J. G. Holmes, D. G. James, E. G. Jenner, E. D Jones, J. D. S. Knight, A. G. Leatham, P. F. Lucas, D. W. R. Lyle, M. B. McIlroy, I. A. Magnus, P. R. A. May, E. T. G. Meade-Waldo, C. M. Monro, M. W. L. Mutch, E. W. Nation, G. A. Newsholme, T. J. S. Patterson, A. N. Pearson, P. K. Robinson, G. H. Seale, K. W. Symons, J. M. Thomas, W. E W. Tilleke, J. Upsdell, D. P. Wheatley, R. A. Womersley, K. A. A. Wray, M. F. T. Yealland. *Women:* E. M. Davies, M. Farquharson, M. H. Jordan, E. M. Kingsley-Pillers, S. M. Martin.

UNIVERSITY OF MANCHESTER

The following candidates have been approved:

FINAL M.B., CH.B.—H. W. Ashworth, W. C. Astley, D. J. Atherton, George Bennett, Ethel F. Caplan, Dorothy I. Elkin, G. V. Feldman Doreen H. Hayes, Margaret Laycock, H. B. Marsden, Joan E. Nuttall, M. G. Saunders, L. Shuck, Cecilia M. Smellie, Margaret M. Tutton, P. O. Yates.

UNIVERSITY OF WALES

The following candidates in the Welsh National School of Medicine have satisfied the examiners:

M.B., B.CH.—*Pathology and Bacteriology:* T. J. Anthony, A. J. Barry, A. H. Baynon, D. K. L. Davies, G. E. Davies, E. D. Edwards, D. B. Harries, J. M. Hughes, S. T. James, A. S. Jones, M. G. Jones, Nest Jones, R. L. H. Jones, Mary Lawrence, Bernice G. Lewis, J. M. Lewis, R. Medlicott, G. Owen, Barbara M. Parker, Beryl P Roberts, K. L. Roberts, S. L. Stone, W. D. C. Thomas, J G. Tomkins, D. M. Watkins.

NATIONAL UNIVERSITY OF IRELAND

The following candidates have been approved at examinations held in December:

M.B., B.CH., B.A.O.—Margaret Barry, Geraldine Casey, C. Conran, P. Conran, J. F. Cox, J. J. F. Donworth, M. D. Doyle, D. W. Harvey, J. A. Jervois, P. Kelly, P. O'Donovan, Margaret P. O'Sullivan, Noel G. Roche, J. C. Symons.

M.CH.—M. J. Kelleher, M.B., B.Ch.

D.P.H.—J. Russell, M.B., B.Ch.

ROYAL COLLEGE OF SURGEONS OF EDINBURGH

At a meeting of the College held on Dec. 19, Prof. R. W. Johnstone, President, in the chair, the following who passed the requisite examinations were admitted Fellows:

R. S. Barclay, M.D.; Marjorie R E. Boyd, M.D.; R. B. W. Cole, M.B., B.S.; Leonard Goodman, M.R.C.S., L.R.C.P.; S. W. G Hargrove, M.B., B.Ch.; L. W. Hefferman, M.R.C.S., L.R.C.P.; Mary K. Lawlor, M.R.C.S., L.R.C.P.; F. J. Lorriman, M.D.; Gardiner Mitchell, M.B., Ch.B.; D. R. K. Reid, M.B., Ch.B.; Paul Steiner, M.R.C.S., L.R.C.P.

Medical Notes in Parliament

Immunization of Children in Scotland

On Dec. 8 Mr. A. EDWARDS asked the Secretary of State for Scotland whether the figure of 840,000 immunized children in the Summary Report by the Department of Health for Scotland for the year ended June 30, 1944, included all children immunized in 1940, 1941, 1942, and 1943.

Mr. JOHNSTON: Yes, Sir. I regret that through an oversight on this occasion an adjustment was not made to allow for children immunized in previous years who were no longer under the age of 15 in 1943. This adjustment cannot be precisely calculated, but it is estimated that the average number of immunized children under the age of 15 in 1943 was about 700,000. Correspondingly the number of non-immunized children in 1943 would be 540,000, not 400,000 as stated in the Summary Report. These figures make no allowance for the unknown but relatively small number of immunizations performed by private doctors outside local authority arrangements. In place of the incidence rates quoted in that report, therefore, it appears that approximately 1 in every 160 non-immunized children took diphtheria during 1943 as compared with only 1 in every 430 immunized children. The case-mortality rates quoted in the report of 1 death in 18 cases for non-immunized children as compared with 1 death in 163 cases for immunized children are not affected by this adjustment.

British Prisoners-of-War in Siam

On Dec. 19 Sir JAMES GRIGG, replying to Sir Alfred Knox, said that from the information received from the British prisoners-of-war in Japanese hands rescued by the United States Navy from the sea last September, there was no doubt that the Japanese military authorities decided to construct the railway and road between Siam and Burma with all speed and regardless of the conditions under which the prisoners worked or of the cost in human life. After the completion of the railway, conditions improved somewhat, but they were far below anything which would be regarded as reasonable for our prisoners-of-war in Europe. The men, however, had adapted themselves and become to some extent inured to these lower standards, while many of the conditions which caused such heavy sickness and death rates in the jungle camps did not obtain in the rear camps to which the men were withdrawn. As a consequence there was apparently a very marked fall in the death rate, and there was evidence to show that, on the whole, the prisoners were in fair health and good spirits when the rescued men left Siam about July, 1944. In the rear camps round Banpong their huts were weatherproof, cooking and sanitary arrangements were hygienic, and there was some space and opportunity for exercise. The Protecting Power had been asked to make the strongest possible protest regarding the past conditions in Siam and Burma. With regard to present conditions, we should continue to press the Japanese to allow all camps in Siam and elsewhere to be inspected regularly by neutral observers, to make arrangements which would enable the Red Cross to send adequate relief supplies for all our prisoners, to improve the mail service to and from prisoners, and to notify within a reasonable period all casualties, past, present, and future, affecting British prisoners-of-war.

Manufacture of Penicillin

Sir ANDREW DUNCAN said on Dec. 20 that many British manufacturers were now manufacturing penicillin or making arrangements to do so. Any firm licensed for this purpose under the terms of the Therapeutic Substances Act would be given every encouragement to manufacture. It was premature to give estimates of our production of penicillin in a year's time, but this would be substantial, though less than American production. It would not only meet military needs but provide large quantities for civilian purposes.

Leprosy in the Colonies

On Dec. 20 Dr. SUMMERSKILL asked how many people suffered from leprosy in the Colonies, and what proportion were treated in leper settlements. Col. STANLEY replied that statistics were not available, but it was known that in those Colonial territories where the disease had the largest incidence only a small proportion of the sufferers were in settlements. The policy generally followed was one of voluntary as opposed to compulsory segregation. In certain territories a stage had been reached when considerable numbers were being discharged annually from such settlements, with the progress of the disease arrested, and returned to their villages, under observation.

Medical News

The Negotiating Committee appointed by the B.M.A., the Royal Colleges, and other bodies will have its first meeting with the Ministry of Health on Jan. 12.

Lieut.-Col. C. H. Stuart-Harris will deliver the Goulstonian Lectures at the Royal College of Physicians, Pall Mall East, S.W., on Tuesday and Thursday, Jan. 16 and 18, at 2.30 p.m. Subject: "Influenza Epidemics and the Influenza Viruses."

The Medical School of St. Thomas's Hospital has vacated the temporary premises at Godalming and will re-open in the Medical School buildings in London on Jan. 9. The linked St. Thomas's Hospital at Hydestile will continue to cater for the major part of in-patient clerking and in-patient dressing.

The next clinical meeting of the Whipps Cross Hospital Medical Society will be held on Jan. 12 at 8.30 p.m.

There will be a meeting in London of the Society of Thoracic Surgeons of Great Britain and Ireland on Thursday and Friday, Jan. 25 and 26. At 2 p.m. on Thursday, at the Royal Society of Medicine, Wimpole Street, W., the subjects for discussion will be constrictive pericarditis, and foreign bodies in the air passages. On Friday morning at 10 a.m. at Manson House, Portland Place, W., there will be a discussion on the treatment of carcinoma of the bronchus. Members of the Allied military medical services and surgeons in the E.M.S. will be welcome.

The Sheffield Fabian Society has arranged a public debate on a national health service to be held on Saturday, Jan. 27, at 3 p.m. in the City (Memorial) Hall, Sheffield. The opening speakers will be Dr. D. Stark Murray (vice-president, Socialist Medical Association) and Dr. A. Macrae (assistant secretary, British Medical Association).

Dr. J. G. Porter-Phillips, F.R.C.P., has been elected a member of the Governing Body of Bethlem Royal Hospital on his retirement from the post of physician-superintendent, which he has held for thirty years.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* infectious diseases were generally lower in incidence; notifications of diphtheria were fewer than last week by 150, whooping-cough by 122, dysentery by 53, and scarlet fever by 15. Measles notifications rose by 79. One case of smallpox was notified from the metropolitan borough of Hackney.

There were no large local variations in the incidence of scarlet fever. The fall in whooping-cough was fairly general throughout the country; Lancashire reported 21 fewer cases of this disease. Diphtheria notifications were the lowest for fifteen weeks; Lancashire reported 53 fewer cases than last week, Durham 32, and Cheshire 20. The rise in measles was the smallest for the past thirteen weeks, and there were wide local variations.

Dysentery notifications at 201 were the lowest for the past eighteen weeks. There were 24 new cases notified in Dorsetshire, Sturminster R.D. London returned 27 cases, Lancashire 26, Warwickshire 16 (Birmingham C.B. 14), Glamorganshire 15 (Cardiff C.B. 13), Essex 12, Northumberland 10.

In *Scotland* more than 100 cases of measles were notified for the second consecutive week. There were 23 more cases of dysentery than in the previous week; the largest returns were Glasgow 41, Lanark County 13, Edinburgh 11.

In *Eire* diphtheria notifications fell by 20, and those for measles rose by 24.

In *Northern Ireland* there was a slight drop, 13 cases, in the high incidence of measles, and there were also 5 fewer cases of scarlet fever.

Diphtheria

According to returns received from all but a few local authorities in England and Wales, 2,243 cases of diphtheria among immunized children were notified during the first half of this year, as against 6,743 among non-immunized children. The number of deaths among immunized children was 16, compared with 368 among children not so protected.

Week ended December 23

The returns of infectious diseases in England and Wales during the week included: scarlet fever 1,906, whooping-cough 1,317, diphtheria 456, measles 8,433, acute pneumonia 715, cerebrospinal fever 33, dysentery 173, paratyphoid 3, typhoid 5.

No. 50

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Dec. 16.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1944					1943 (Corresponding Week)

ANY QUESTIONS?

Hypertension and Blood Donation

Q.—*Should hypertensive patients offer themselves as regular blood donors? If epistaxis and menorrhagia are considered "safety valves," why not blood donation? I have a patient aged 39 with a blood pressure of 210/120 and menorrhagia. In the opinion of a specialist it would be very unwise to do anything about the menorrhagia.*

A.—It is a well-known saying that many a patient has been saved from a cerebral haemorrhage by heart failure. It is equally true that a severe anaemia may mask an underlying hypertension, and most haematologists have had the embarrassment of seeing the symptoms of anaemia replaced by those of hypertension as a result of iron or liver therapy. Neither heart failure nor severe anaemia could be taken as therapeutic objectives, however, and anything less than a severe anaemia has little effect on hypertension. Bleeding is useful in hypertensive encephalopathy, but it is of little value in the ordinary course of the disease. There is always the possibility that a blood donation will be followed by fainting or some grosser vascular accident, which will be blamed on the procedure. A blood transfusion centre is no place for the unhealthy, and as a general rule we should deprecate using hypertensive patients as regular blood donors.

Chemotherapy of Malignant Endocarditis

Q.—*Would you clarify the question of treatment of malignant endocarditis, including subacute bacterial, in regard to sulphonamides and penicillin.*

A.—The response of subacute bacterial endocarditis to any form of chemotherapy is very variable, much depending on the stage of the disease and the sensitivity of the responsible organism to the drug used. Various sulphonamides have been employed for some years past with only occasional lasting benefit. If the particular streptococcus is sufficiently sensitive to the drug, blood cultures become negative and the general condition improves, but recurrence after cessation of treatment is the rule. The simultaneous administration of heparin to prevent further fibrin deposition on the vegetations gives the drug a better chance, but involves a serious risk of causing cerebral haemorrhage. Prolonged treatment with massive doses of sulphadiazine has recently been advocated. Ideally, choice of drug should be determined by tests of the sensitivity to it of the patient's own streptococcus.

The treatment of subacute bacterial endocarditis with penicillin was the subject of recent comment in this *Journal* (Sept. 16, 1944, p. 380). Penicillin has undoubtedly a more powerful antibacterial action on the streptococci concerned in this disease than any of the sulphonamides, but the sensitivity of different strains varies enormously (M. H. Dawson *et al.*, *Proc. Soc. exp. Biol.*, N.Y., 1944, **56**, 101), some being so resistant that treatment cannot be expected to succeed. This doubtless accounts in part for some of the failures reported; on the other hand, among cases treated in the U.S.A. there has been a substantial proportion of apparent cures—or perhaps it would be safer to say prolonged remissions. The total dose required may be 5,000,000 units or more, and since this amount will save a number of lives endangered by other infections it has not been thought justifiable to treat subacute bacterial endocarditis in this country until the supply position improves.

The same considerations apply to the treatment of more acute forms of bacterial endocarditis. It is well known that this complication greatly worsens the prognosis in the penicillin treatment of septicaemia due to any of the pyogenic cocci; in fact the existence of an endocarditis is the commonest explanation of failure in treating staphylococcal septicaemia. Its recognition might be held to call for increased dosage, but there is no evidence that this will succeed.

Functional Uterine Haemorrhage

Q.—*Are oestrogens indicated in the treatment of functional uterine haemorrhage? If so, what are the rationale of their use, their dosage, and times of administration?*

A.—Functional uterine haemorrhage is generally believed to be associated with a failure of ovulation and thus with failure of development of the corpus luteum. The endometrium is thus constantly under the influence of oestrogenic hormone. The primary defect is believed to be a disorder of the anterior pituitary. It is difficult to understand how oestrogenic hormones can benefit such cases, and the most hopeful line of treatment seems to be the administration of pituitary gonadotrophic hormones. Clauberg has claimed success in these cases with "oestrogen shock therapy." The rationale of this is based on the fact that a single large dose of oestrogenic hormone may be followed first by inhibition of the anterior pituitary and storage of the gonadotrophic hormone, and then by release of this hormone and ovulation. This has been confirmed experimentally in animals. A single large dose (100,000 to 200,000 units) of oestrogenic hormone is given a few days after cessation of haemorrhage in cases where bleeding is intermittent.

In assessing all methods of treatment of functional uterine haemorrhage—and the large number of substances that have at one time or another been used for this condition suggests that the ideal method remains to be found—it must be remembered that spontaneous recovery is no uncommon occurrence.

Vitamin K and Post-partum Haemorrhage

Q.—*Is there any recent evidence regarding the value of vitamin K in the prevention of post-partum haemorrhage and haemorrhagic disease in the newborn? What is its value in purpura haemorrhagica? What dosage is suggested?*

A.—There is no doubt that the administration of vitamin K to the mother and/or the newborn child prevents the fall in the coagulating power of the blood which commonly occurs during the first week of life. It would be a much harder task to show that vitamin K prevents the occurrence of haemorrhagic disease, just because the disease occurs so rarely. The incidence in the U.S.A. from 1874 to 1934 was apparently fairly constant at 0.5%. To show an improvement on this figure which was statistically significant it would be necessary to treat 10,000 babies with vitamin K. No one has done this up to date. What many authors have tried to show is that the neonatal mortality from intracranial haemorrhage is reduced by vitamin K. This is a very different proposition, since a coagulation defect is probably not the most important factor in intracranial haemorrhage. Nevertheless it is generally believed that the incidence of intracranial haemorrhage is reduced by vitamin K. One dosage schedule recommends the administration by mouth of 20 mg. synthetic vitamin K to the mother before delivery and 5 mg. to the infant at birth; alternatively a single dose of 10 mg. to the infant is equally effective. Other authors have had success with smaller doses. Vitamin K is of no value in post-partum haemorrhage or purpura haemorrhagica.

Ptomaines

Q.—*Is it true that ptomaines are innocuous when taken by the mouth, and poisonous only when injected?*

A.—The name "ptomaines" was given by Selmi to bodies of the nature of diamines isolated by him and others from putrefactive food. Subsequently a number of such bodies were isolated, including *putrescine*, *cadaverine*, and *neuridine*. When injected into laboratory animals most were highly toxic. The majority were prepared between 1860 and 1884, and at that stage of bacteriology it was not unnatural to assume that they were the cause of food poisoning. Hence originated the use of "ptomaine poisoning" as synonymous with "food poisoning." Subsequent investigations showed, on the one hand, that they were only produced as quite *late* degradation products of putrefaction, when the food would certainly be rejected as too nasty to eat, and, on the other, that their toxicity was exhibited only when injected into animals and that by mouth they were almost completely non-toxic. There is no evidence that any of them are toxic to man by mouth. In all food-poisoning outbreaks (except botulism) the food at fault is indistinguishable in appearance, taste, and smell from sound food, while there is no evidence that the consumption of food in any stages of putrefaction is harmful to man unless the food concurrently contains the toxins of specific food-poisoning bacilli. Savage (*J. Hyg.*, Camb., 1921, **20**, 69) repeatedly fed a series of kittens daily with meat or fish allowed to putrefy at different stages, but most with meat in a highly offensive condition. Apart from some loss of weight, there were no symptoms of ill-health.

An important point is that ptomaines are not specific products of particular bacteria, but are merely late degradation products of the protein molecule, produced by a whole series of putrefactive organisms. The expression "ptomaine poisoning," therefore, should never be used, as it implies that food poisoning may be due to degradation products in food without the presence of any specific causative organism. Actually all food-poisoning outbreaks when investigated are shown to be due to the specific products of particular organisms, such as *Bact. botulinum*, Salmonella strains, certain staphylococci, etc. The use of the term "ptomaine poisoning" is to be strongly deprecated as directing attention away from a specific cause to a non-specific causation which has no existence in fact, and which is merely a "Mrs. Harris" of medicine.

Anaesthetic for a Primigravida with Tuberculosis

Q.—*A primigravida undergoing A.P. treatment for pulmonary tuberculosis is expecting to be confined at an early date. Most authorities advise forceps delivery when the cervix is fully dilated and the head well down in the pelvic cavity. Gas and oxygen is the anaesthetic recommended, but if this is not available what would be the "next best"? Dare we use intravenous anaesthesia (pentothal sodium or evipan)?*

A.—Evipan and pentothal sodium are employed in midwifery, but owing to their depressant action on the respiratory centre their disadvantage is possible difficulty in initiating respiration in the baby. However, there are many reports of the use of such anaesthetics for obstetric operations—even for Caesarean section—without indicating any undue foetal risk. The use of evipan for low forceps delivery and perineal repair in general practice is described by K. M. Robertson in the *British Medical Journal* (1941, 1, 815). Nevertheless, in this particular case great care would be necessary, and a dose sufficient for the purpose might cause respiratory embarrassment in the mother, if not in the child. Perhaps local analgesia, by infiltration of the perineum, vulva, vaginal walls, and paravaginal tissues, including levatores ani, would be the ideal for this patient, but it would require some experience in the technique. The case seems to call for special care, and there is every indication for delivery under hospital conditions with all facilities available—including the services of an expert anaesthetist. In such circumstances there should be no real difficulty, and cyclopropane would be very suitable; indeed many would regard it as the anaesthetic of choice.

If it is quite impossible to arrange for delivery under favourable hospital conditions, there is something to be said for open ether—on the grounds of safety. It is usual to regard this anaesthetic as being contraindicated in pulmonary tuberculosis, but many experts no longer subscribe to this view. In a case of this kind the choice of anaesthetist is more important than the choice of anaesthetic, and I would repeat that the patient should be delivered in a hospital adequately staffed and equipped.

Chronic Blepharitis

Q.—*What is the best treatment of chronic blepharitis in a young adult who has no refractive errors? Triple dye in spirit, silver nitrate 1% to 10%, and golden eye ointment have been tried without much improvement. The seborrhoeic scalp has been treated with sulphur and salicylic ointments well massaged into the roots, but again without any permanent success. No penicillin is available.*

A.—Chronic blepharitis is apt to be obstinate and may not clear for several months. General treatment should aim at improvement of the patient's condition and hygienic surroundings, and avoidance of too much sugar. Local treatment involves attention to any infection of the tarsal glands, and expression of such as are choked by pressure between a finger outside and a glass rod inside the margin of the lid. Complete epilation helps in obdurate cases. Attention should be given to any lacrimal sac infection. Before the application of any ointment or paint can be effective, all crusts must be removed thoroughly with warm H_2O_2 or sodium bicarbonate 2% lotion. The lid should be dried, and then the following ointment applied: ung. hyd. ammon. dil. 1%, or ung. resorcin 1%. A good excipient is equal parts of lanoline and vaseline, but it must be fresh; a rancid ointment keeps the condition alive. Of the paints, liq. tinctorum is best, but iodine 2% and optochin 2% have been found useful. Silver nitrate 1% or 2% applied not more than three times a week clears up any raw spots. As a last resort a vaccine may be tried.

Facial Hair and Sex Hormone

Q.—*A man aged 23 has almost complete lack of facial hair growth and shows some retardation of normal hirsutism generally. He is otherwise well developed and healthy; external genitalia within normal limits, and sexual functions appear to be normal too. The complaint is the psychological effect of the deficiency, of which he is acutely aware. Is hormone therapy advisable, and if so, what?*

A.—One occasionally meets with the apparent anomaly of subnormal facial hair growth together with normal sex function and development, and it must be attributed to local lack of response or sensitivity to the normal level of androgens in the blood. It is sometimes possible to overcome this refractoriness by the administration of exogenous androgens, and the best method of securing a local concentration is probably by inunction of unguentum testosterone, 25 mg. per gramme. It is unlikely that this method of administration could have any untoward effects, but large doses of testosterone intramuscularly might temporarily suppress testicular function by inhibiting the secretion of pituitary gonadotrophic hormone. In practice it is doubtful whether this really constitutes a risk, especially if therapy is intermittent.

Morphine Administered by First-aiders

Q.—*Are there any contraindications for giving morphine to seriously injured miners? The Home Office has agreed to authorize first-aid men employed in or about mines to administer the drug; it will be used in an ampoule-syringe form, which will ensure that the needle is clean, that no overdose is given, and that there is no morphine left about. Are there any parts of the body which they should always select if available? Will it be sufficient to keep a D.D.A. book in the surgery, or should I keep one in each rescue station or colliery where the morphine is stored?*

A.—Morphine is given to an injured person to relieve pain, diminish shock, and calm the mind. Sometimes it has an initial effect of exciting the imagination, but its usual action is to dull sensibility and produce mental quietude. The chief danger from morphine is due to the fact that it depresses the respiratory centre; it should not, therefore, be given to those suffering from serious head injury or severe shock attended by depression of that centre, as shown by slow and shallow respiration. The young and the old are much more sensitive to the drug, and the following remarks must be taken to apply to those between the ages of 18 and 60 years.

In cases attended by pain and unaccompanied by any respiratory depression the drug is usually tolerated well; in such cases it is quite safe to administer a quarter of a grain of morphine tartrate, and if the pain still persists this dose can safely be repeated within two or three hours. Even in the absence of pain it would be advisable to give a similar dose in cases of fracture prior to any movement of the patient which is likely to give rise to pain. The injection can be given subcutaneously or intramuscularly into any easily accessible part of the body. If given into the limbs it is well to choose the proximal part, for there the circulation is likely to be better and absorption quicker. The lateral part of the abdominal wall is also a suitable place for injection. Intravenous injection should only be done by the doctor.

The last point raised is, I think, dealt with under 11D of the Dangerous Drugs Regulations, 1937, which requires that a separate register shall be kept in respect of each set of premises at which the authorized person carries on his business or profession. Clearly, it is desirable, in order to avoid confusion, that a record shall be kept at each colliery or rescue station where the morphine is stored and used.

Mixed Inhalant Solutions for Allergy

Q.—*Does it suffice to give a mixed inhalants solution in a case of allergy, or is it advisable to determine the exact causal agent and then give an appropriate desensitizing solution?*

A.—The mixed inhalants solution contains the usual common inhalant causes of allergy as determined by skin tests—feathers, dust, orris root, and animal hairs (horse, dog, and cat). It is advisable to test each patient individually because (1) it may be necessary to add pollen if the patient reacts to pollen, or to use the combined pollen vaccine if there is a large reaction; (2) it may be necessary to add other occupational dusts if the patient's job suggests such a sensitivity, such as flour-dust for a baker or miller, tomato fungi for those affected by hot-house tomato plants, or insecticides in agricultural workers; and (3) it is essential to find out how sensitive the patient is: if very sensitive, the weak "initial" solution must be used and the irritants removed so far as possible; in only slightly sensitive cases the stronger "continuation" course can be used to begin with. The initial solution must always be used in cases very sensitive to horsehair. It is rare for a patient to react to one irritant alone. In such cases it may be wise to give the exact desensitizing solution, but if the specific causative substance is contained in the mixed inhalants solution it is probably better to use this, as the other proteins contained may act as additional non-specific desensitizers.

Myocardial Degeneration

Q.—*A patient aged 74 has had two attacks of severe oedema of the lungs since 1940. Treatment with morphine and oxygen with the B.L.B. apparatus has brought relief. A third attack was more severe, and the patient seemed to respond to treatment only when an injection of nikethamide had also been given. The outer border of precordial dullness is 4 inches from the middle line. There is a presystolic murmur. The blood pressure is 145/80. I would welcome advice about preventing such attacks.*

A.—These attacks are usually provoked by over-activity. There is, no doubt, intrinsic myocardial degeneration in this case, and so the deterioration is likely to be progressive, although this may be slow at the age given. If definite over-activity has directly brought on an attack, this must be avoided. If the attack has come at night, the day before may have been too full. During sleep the patient should be well propped up if possible, and a late meal should be avoided. Distension of stomach, bowel, or bladder may be a provoking cause. The daily administration of 2 grains of the powdered leaf of digitalis may increase cardiac efficiency. Morphine in quite small doses often suffices in the aged.

Rosacea

Q.—*Some years ago I read a note in the* JOURNAL *on the occurrence of red noses in adolescents. A girl of 17, in perfect health, of fine physique and good looks, is occasionally afflicted in this way, the tip of her nose only being affected.*

A.—The pathogenesis of rosacea is complicated and probably involves a number of different factors, such as a seborrhoeic disposition, gastro-intestinal dysfunction, including achlorhydria, and according to some authorities a psychological factor. Thus R. Klaber and E. Wittkower (*Brit. J. Derm. Syph.*, 1939, **51**, 501) in a comprehensive review suggest that rosacea may result from emotional changes, and this may explain the phenomena in the case related above.

Left-handedness

Q.—*What is the proper attitude to adopt to a left-handed child aged 4½ years (a) by parents, and (b) by kindergarten school-teacher? Is it true that insistence on using the right hand may cause the child to develop a stammer or some other psychological aberration—e.g., obstinacy?*

A.—If the child is predominantly left-handed he should be allowed to continue so both by parents and by kindergarten school-teacher—if his inclination is to write with his left hand he should not be forced to use his right hand. When the predominance of the left hand is clearly defined, outside interference may lead to a stutter, the speech defect resulting from the attempt at adaptation to right-handedness when the inclination and probably the architecture of the cerebrum are towards left-handed predominance. There is no reason to suppose a relationship between left-handedness as such and stuttering; the important factor is the *enforcement of right-handedness* in a left-handed child, and many well-authenticated cases have been recorded in which stuttering developed as a result of attempting such a change. Similarly, minor psychological abnormalities may result in some children owing to frustration in the use of the left hand.

It should be stated, in general, that more exact definition of left-handedness is still required, as well as more satisfactory tests.

Action of Phenobarbitone

Q.—*Barbiturates containing the phenyl radicle are believed to depress particularly the motor cortex, hence their use in epilepsy. But phenobarbitone appears to be the barbiturate most commonly used as a general sedative. Would not subhypnotic doses of hypnotics, such as buto-barbitone, be more rational?*

A.—Experience with phenobarbitone and the other barbitones shows that the action of phenobarbitone is by no means confined to the motor cortex. The effect of buto-barbitone is a hypnotic one, and it is very useful for procuring sleep. Phenobarbitone is probably as widely used for its sedative as for its anticonvulsant action, and clinicians have a clear picture of its double effect. In epileptics it is valuable in controlling fits, with very little of the depressant effect of bromides, unless comparatively large doses of, say, 2 or 3 grains are used. With these large doses patients sometimes complain of feeling drowsy in the afternoons and evenings. Anxious patients, on the other hand, describe a very beneficial result from smaller doses of phenobarbitone, which in them has a prolonged and mild hypnotic effect, causing a diminution in their mental symptoms. This effect, which is not produced so easily by other barbiturates, is so evident that some say that phenobarbitone has a greater action on neurotic subjects than on others. This is unlikely to be the case—the sedative action is simply more evident in them. It is because of this that phenobarbitone is so widely used.

Coated Tongue

Q.—*What is the basic cause of a coated tongue? Why is it worse on waking up in the morning, and especially after an upset digestion, fevers, etc.?*

A.—The chief causes of furring of the tongue are toxaemia, diminished friction from inadequate mastication, and inadequate salivation. The fur is a collection of desquamated epithelial debris and minute food particles which have become entangled in it. A small amount of fur which tends to collect overnight is compatible with perfect health, and is the rule rather than the exception in adults, especially smokers. Excessive proliferation of the papillary endothelium occurs in toxaemic states. This, combined with the dry tongue of dehydration, is sufficient to cause a thick, offensive fur. A pretty example of fur collecting because of poor mastication is seen in cases of trigeminal neuralgia. In these patients furring is seen only on the side of the tongue that is painful and protected from friction.

LETTERS, NOTES, ETC.

Dose of Pethidine

Dr. F. PRESCOTT (London, N.W.1) writes: In your "Any Questions?" of Nov. 18 (p. 687) the dosage of pethidine is given as 25 mg. to 50 mg. This dose is, generally speaking, much too low. The optimum effective dose is of the order of 100 mg., and in the case of severe pain this is best given parenterally. In some cases 150 mg. to 200 mg. is needed. It would be better to give the range of dosage as 50 mg. to 100 mg. orally or parenterally, increased if necessary to 200 mg. This is the opinion of Batterman (*Arch. intern. Med.*, 1943, **71**, 345), who has studied the effect of pethidine on over 1,000 patients. Rarely does 25 mg. relieve severe pain. The correct dosage is important when using a new drug, because if the dose recommended is too low the drug is liable to be discredited. In the case of pethidine this would be a pity, as it appears to be a very valuable drug. The answer does not bring out sufficiently clearly the most important use of pethidine—namely, the relief of pain associated with spasm of smooth muscle. It is less effective in relieving pain of neuritic or muscular origin. The use of pethidine in obstetrics is not mentioned in the answer. There are now a number of papers on this in the literature (*British Medical Journal*. 1944, **1**, 176, 179; 1944, **2**, 498; *Amer. J. Obstet. Gynec.*, 1943, **45**, 318, 320; 1944, **47**, 93). The dose is 100 mg. intramuscularly, repeated an hour later, with further injections of 100 mg. at intervals of 2 to 4 hours. Pethidine can be combined with scopolamine or barbiturates.

Nausea and Vomiting of Pregnancy

Dr. MARGARET ROUND (medical officer in charge, Evangeline Booth Hospital for Women and Children, Madras Presidency) writes: About 1932 I read in the *British Medical Journal* that it is of great help to pregnant women to give them a calcium preparation—e.g., calc. lactate—5 gr. daily throughout the pregnancy, and to give quinine hydrochlor. (or sulph.) 2 gr. daily as well as the calcium during the last six weeks of pregnancy. I began that procedure then, and have found that complications of pregnancy, particularly vomiting, cramps, eclampsia, and overdue labour, are eliminated in those who follow the treatment. When a patient first comes to me with nausea and vomiting I give intravenous calcium gluconate, 10 c.cm. of 10% solution, daily if necessary; very seldom are more than three or four injections needed. One case of hyperemesis in England (2 years' practice) failed, but that cleared up promptly when I suggested that hospitalization was the only thing left for us to try. In five and a half years in my present appointment at the Salvation Army Hospital for Women and Children, Nidubrolu, I have contacted many pregnant women—322 new cases in the last twelve months. There is a small percentage with nausea and vomiting. I have not known intravenous calcium gluconate not to give relief. We have a large number of women brought to us at the last moment with severe albuminuria and eclampsia. The first step in the treatment is to give intravenous calcium gluconate, then follow with the usual stomach and bowel wash and mag. sulph. Our mortality rate is very low for eclampsia. In cases having the calcium treatment from the early months there has been no albuminuria and no further nausea and vomiting after beginning the calcium. When quinine is given in the last six weeks as well as the calcium, delivery usually takes place two to seven days before the calculated date for delivery. Primiparae as well as multiparae deliver in from four to eight hours; the time is definitely shortened, apprehension lessened, and no tears are produced by the shortened labour. If one believes all one reads in medical journals these days, calcium has fallen into disrepute. I have neither time nor equipment to find out why calcium does help very definitely nausea and vomiting of pregnancy, but my patients can show by their well-being that they are helped.

Colt or Filly?

Dr. L. KILROE (Rochdale) writes: Dr. Hobart Nixon in his letter (*Journal*, Dec. 16) appears to have overlooked one gift which Rocksand displayed in the remarkable performance he is credited with in that communication—namely, female impersonation; otherwise, how could a colt compete in and win the Oaks?

The Young Married Doctor

Dr. A. W. N. DRUITT writes: The letter on the young married doctor (Sept. 23, p. 419) prompts me to add a further statement, that it is not only the junior hospital officers who are denied, and will be denied, the privilege of living with their families, but the senior officers too. In practically all hospitals (a small percentage being excluded) no accommodation is made for the wife of a senior officer, and I regret to say that even in the modern hospitals, built just before the war, the resident surgical officer is given one small room like the other junior house officers, and maybe expected to hold that appointment for anything up to two years or more. It is certainly time that hospital authorities provided better "living" accommodation for its "resident" house officers and, if necessary, their wives.

THE EVOLUTION OF MODERN THERAPEUTICS*

BY

Sir W. LANGDON-BROWN, M.D., Hon.D.Sc., F.R.C.P.

Emeritus Professor of Physic in the University of Cambridge

It is not only quite logical that treatment should come last in a textbook description of diseases; it also follows the historical sequence of our knowledge. Fifty years ago it must be admitted that this section was very summarily dealt with, often consisting merely of vague statements. Nor is this surprising, when we were taught that in treatment "the first thing is diagnosis, the second diagnosis, and the third diagnosis." We should agree that the first thing is diagnosis, but if treatment stops there we should rightly find a dissatisfied patient.

Let me go back very briefly to the beginning. In Ancient Greece we find two cults side by side: the Aesculapian, with its methods of psychotherapy and suggestion; the Hippocratic, observational but dominated by the doctrine of the four humours—not much stress on medicines, though Hippocrates prescribed ox liver for anaemia. But both cults laid great emphasis on cleanliness, fresh air, attractive surroundings, and, where practicable, exercises. Galen placed much more reliance on drugs, as we are reminded by the persistence of the term "galenicals" in pharmacy. He carried the doctrine of humours to the point of saying that if, for instance, the patient was hot and wet, the appropriate treatment was cold and dry, thereby showing himself more of an "allopath" than the homoeopaths declare us to be.

After Galen comes the crash, and any attempt at medical science virtually vanishes from Europe. The reason is clear: in the Roman Empire, which was synonymous with the civilized world, physicians came to be treated as slaves, and medicine can flourish only in an atmosphere of freedom. Hippocratic medicine, it is true, flickered still at Salerno; for the rest, it was just kept alive by the Arabs. Otherwise there was a reversion to magic and witchcraft, with no real advance for more than a thousand years. True, a number of useful drugs derive from witchcraft and folklore, such as belladonna, hyoscyamus, aconite, valerian, cinchona, and digitalis.

The Beginnings of Scientific Medicine

Scientific medicine begins with the Renaissance—with the anatomy of Vesalius, the experimental methods of Gilbert, the physiology of Harvey, and the morbid anatomy of Malpighi. But their application to clinical medicine could scarcely be made effective while chemistry remained in such a confused and elementary condition. The crude attempts of the iatro-chemists, such as Sylvius, came to very little. Meanwhile observational clinical methods made advance under Glisson, Willis, and Sydenham. Yet treatment could hardly advance until a more scientific study of drugs was made in the middle of the 18th century by William Heberden, who lectured on materia medica at St. John's College for ten years and did his best to found a rational pharmacology.

Still, it remains true, as Sir Francis Fraser says, that the beginning of the 19th century found treatment much the same as 1,500 years previously. The fundamental idea of disease as something added to the body, which had to be got rid of, still ruled the practice of therapeutics, which was therefore largely of an eliminative character—emetics, purgatives, diuretics, diaphoretics, and bleeding. As a better appreciation of the complex changes in disease developed, doubts gradually arose as to the wisdom of such heroic efforts to expel the disease from the body. It is not fanciful to see in this idea of expulsion an unconscious persistence of the more primitive idea of disease as due to demoniacal possession or influence.

With the 19th century came new methods of diagnosis—auscultation and percussion—which certainly made medicine more scientific. This led to a close comparison between the physical signs detected during life and the lesions revealed post mortem. In this way a solid body of knowledge was built up, but it led to some neglect of therapeutics by diverting attention from the beginnings of disease to its end-results, which produced a nihilistic attitude towards treatment by drugs. A rather comic sidelight is thrown on this aspect, that when I became medical registrar at Bart's the post-mortem book was still labelled "Register of Complete Cases." There you have it: no case complete until the necropsy is reached! Meanwhile anaesthetics and antiseptics were enabling surgery to shoot ahead.

It was not until the last quarter of the 19th century that therapeutics began to take a new course. Although salicylate had been synthesized for commercial purposes in 1874, the first synthetic preparation used clinically was antipyrine, or phenazone as it is now more usually called, which was prepared in 1883 by Filehne, whom I remember when he came here a few years later to work at antipyretics. The name "phenazone" has the advantage of reminding us that it, like salicylate, is a phenol derivative and therefore contains a benzene ring. It is very interesting to observe this in the earliest artificial products designed to influence metabolism, for a good many years were to elapse before it was found that a benzene ring or rings were an essential basis for products formed by the body to regulate its own metabolism. Thus adrenaline contains one such ring and thyroxine two, while the sex hormones and vitamin D contain four, condensed into the so-called phenanthrene ring.

The Biological Approach

The last decade of the 19th century saw yet a newer approach in therapeutics—the biological one, as seen in immunology and endocrinology. G. R. Murray introduced thyroid therapy in 1891, and active extracts of the adrenals and pituitary followed within the next few years. Hitherto the ductless glands had been regarded as excretory in character, the elimination theory cropping up again in a new guise. The bloated aspect of the myxoedematous patient might well suggest this; but Addison's disease was regarded as a failure on the part of the adrenals—anatomically so close to the kidneys—to detoxicate the body, until Sir Humphry Rolleston in his Goulstonian Lectures for 1895 adduced the evidence of its being an "atony" due to the loss of an internal secretion, the existence of which he predicted. And even quite recently hyperparathyroidism was attributed to a failure to eliminate guanidine. However, the conception of internal secretion, hitherto vaguely and fitfully held, was firmly established by Starling's hormone theory, which he put forward in his Croonian Lectures for 1905. This, by showing that the body prepared active chemical substances for its own use, had a marked influence in restoring belief in the efficacy of drugs to influence its reactions. But no wave of advance is without a backwash, and the early triumphs of thyroid therapy misled us into thinking the problem simpler than it has proved to be. Moreover, a new polypharmacy arose, and I have seen prescriptions of an extraordinary conglomeration of animal extracts, quite unrelated to any evidence of their activity. Such abuses were a partial justification for Swale Vincent's sweeping declaration that organotherapy was administration of extracts of unknown value to a credulous patient by a still more credulous physician! Fortunately a more scientific attitude prevails to-day, and we have also learned not only that endocrines can influence the nervous system but that the converse is also true.

---

* A presidential address to the Cambridge Medical Society.

The other great advance in biological therapeutics—immunology—was, of course, an extension of the old empirical treatment of smallpox, first by inoculation and then by vaccination. The bacterial conception of disease gave a great impetus to research on these lines. Pasteur's work on rabies was the first scientific approach, but 1892 saw the early triumph of diphtheria antitoxin, and I recall with interest that two years later I was clinical clerk to the first patient to be treated by it in this country. You will not expect me to deal with the niceties of active and passive immunity. It would generally be agreed now that the passive immunity conferred by sera is suitable for acute diseases, while active immunity achieved by vaccines is principally useful in prophylaxis. Vaccines for established disease have, on the whole, proved disappointing, and I expect that most of my hearers find they are using them much less than 10 to 20 years ago. Routine inoculation by normal intestinal flora is, I hope, discarded: after all, it is a poor bowel that can't grow anything! In parenthesis it is an entertaining illustration of the changed point of view to read again Bernard Shaw's *Doctor Dilemma*; its contempt for clinical medicine and its emphasis on the marvels of opsonins read strangely to-day; for whoever hears of opsonins now? Nothing becomes out of date so quickly as the very up-to-date. Conclusions in clinical observations are difficult to reach, but, once achieved, they have a way of persisting. Thus in my professional lifetime the laboratory has given three different interpretations of Addison's disease, but no one has surpassed his clinical description of it.

Recognition of Deficiency Diseases

But to resume my main thesis: immunology and endocrinology had as their underlying principle the application of Nature's methods so far as was possible. The next step, for which we had to wait until the 20th century, was the recognition of deficiency diseases—the realization that, as it were, a minus could cause a disease as well as a plus. Not only has their study given us new therapeutical weapons, but it has given us new insight into the chemistry of the cell, which employs vitamins as powerful and essential catalytic agents. Endogenous catalytic agents we had recognized, and Garrod traced most inborn errors of metabolism to a congenital absence of one or another such agent. But here were exogenous catalysts; acquired needs as the biochemistry of the body became increasingly complex. As an example let me take R. A. Peters's work on vitamin B_1. Of all tissues in the body the brain cells are most sensitive to oxygen lack, and this intracellular oxygen is supplied by dextrose. If an overdose of insulin has locked up too much of this for the metabolic needs of the moment the patient is convulsed and then becomes unconscious. This we knew; but Peters showed that vitamin B_1—aneurin—is necessary to the breakdown of dextrose so that its oxygen is presented in a suitable form for the brain cell to accept.

We owe, indeed, a great debt to the biochemist and the organic chemist. The latter has provided us with an enormous number of synthetic remedies, while, linked with the biochemist, he not only has unravelled the complexity of, for instance, the structure of the sex hormones, but has actually produced artificially substances of a simpler constitution and yet more potent than the natural ones. If you ask why did not Nature make them, the answer is ready to hand. The natural product has to be prepared within rigid limits of temperature and *p*H. The laboratory methods would often be fatal to the survival of the cell.

The Action of Drugs: A New Conception

I now come to a line of work which seems to me to have introduced a new conception of the action of drugs and has led to a new generalization: that every nervous stimulus to the tissues is mediated through a chemical reaction. The outline of the history of these researches is interesting. In 1901, soon after the isolation of adrenaline, Langley pointed out that its effect on any tissues was the same as if the sympathetic nerve to that part had been stimulated; but the enormous significance of this observation was not realized for some years. In 1906 Langley and T. R. Elliott independently found it necessary to postulate the existence of a receptive substance between the nerve ending and the tissue supplied. It had long been known that in many instances atropine would block the passage of a nervous impulse, while pilocarpine or physostigmine would facilitate its passage and increase the response. Thanks to Dale and to Loewi, these observations were combined and extended to reach a striking conclusion. It was found that when a sympathetic nerve was stimulated adrenaline was liberated at the post-ganglionic nerve ending. This explains Langley's observation and enables us to realize that the adrenal medulla contains an emergency store of adrenaline to motivate widespread sympathetic effects when necessary. The other nerve endings of the nervous system liberate acetylcholine, which activates the appropriate tissue. Thus we can divide the nerve endings into adrenergic and cholinergic, according as they liberate adrenaline or acetylcholine.

Now when atropine paralyses the vagus, for example, it does so by preventing acetylcholine from getting into the receptive substance, though just as much of it is produced as before; and when physostigmine—or eserine, as it is more usually called—prolongs or intensifies the effect of parasympathetic stimulation it does so by preventing the destruction of the acetylcholine set free. The pharmacology of the future will have to study the natural history of these receptive substances and find out in what way they can be helped by drugs, both positively by facilitating their reactions, and negatively by blocking the way against the entrance of toxins.

Attempts to utilize acetylcholine therapeutically have been disappointing and have led to a search for more satisfactory synthetic substitutes. By varying their composition it might also be possible to produce more selective reactions. Of such doryl—otherwise known as carbachol—and mecholin are examples which have met with some limited success. On the adrenergic side ephedrine and benzedrine are familiar examples of drugs which imitate sympathetic action, though there are several other examples that have hardly come as yet into general use. We are getting to know more about their absorption and fate in the body, and in future more uses for them may be found.

Turning to the other side of such reactions, we find, for instance, in eumydrine and prostigmin synthetic drugs which have a more selective action than their native congeners in blocking or facilitating the action of acetylcholine. Eumydrine, which is the methyl nitrate of atropine, is particularly useful in relaxing pyloric spasm. Like physostigmine, prostigmin prevents destruction of acetylcholine at the end-plate, but for a much longer period. Dr. Mary Walker introduced its use in myasthenia gravis, which we may now attribute to some toxic substance—produced by a diseased or, at any rate, an enlarged thymus—which has a curare-like effect in blocking the end-plate between nerve and muscle. The clearing up of this point has naturally encouraged surgeons to treat myasthenia gravis by thymectomy, and Geoffrey Keynes has performed the operation 28 times. The results are variable but in some cases very successful, though the ultimate elimination of the toxin may not be effected even for several months after operation. It is an interesting example of the biochemist indicating the scientific basis to justify the intervention of the surgeon.

We see, then, that drugs may help or bar the entrance of stimuli into the cell. Another way in which they may have this effect is by adsorption on to the cell envelope: thus the barbiturates oppose the entrance of thyroxine, and it is interesting to recall that practitioners were using them empirically before this action was known. A much more selective action against thyroxine is provided by the new drug thiouracil, but its therapeutic effects are still on trial. Its discovery has, however, called attention to other selective actions against endocrines, such as alloxan against insulin and the temporarily sterilizing effect of sulphapyridine in males, while thallium salts appear to be specific against the whole endocrine system. The only therapeutic value in these latter substances is the possible treatment by alloxan of spontaneous hypoglycaemia from hyperinsulinism.

Chemotherapy

The last great advance, chemotherapy, is so much in the news to-day that I need refer only to certain general principles involved. When, in 1907, Ehrlich put forward his theory of side chains, haptophores, and amboceptors to account for the formation of antitoxins, it was, after a preliminary welcome, rather discounted as the kind of thing a German would evolve out of his own inner consciousness. Yet it contained a germ which very soon grew into chemotherapy, for there was the idea of a chemical substance attaching itself to some link in the invading microbe and thus completely sterilizing it. Salvarsan was the result, and, although it has not fulfilled the expectation of its discoverer that it would cure syphilis in one dose, it has proved to be the greatest advance in the treatment of that disease. Ehrlich, as we know, was profoundly interested in dyes, and it was the *intra-vitam* selective staining by methylene blue which gave him the original idea. This is doubly interesting, since it was the dye industry which gave us sulphonamide. This substance was synthesized in 1908 and employed to increase the fastness of dyes. It was thought that this quality was due to the union of the substance with the protein cells of the wool. Although in 1919 some of such dyes were noted to be bactericidal, no clinical application of this observation was begun till 1930, when prontosil was reported upon favourably in the treatment of erysipelas and Domagk came to the conclusion that it had no effect *in vitro* but acted only in living tissues. Later work shows that the action of the sulphonamides must be regarded not as bactericidal but as bacteriostatic, holding the growth of bacteria up until the natural defences of the body could come into action. We now know more of the way in which this is accomplished, for it has been shown that sulphonamides successfully compete with p-animobenzoic acid for the favours of the cell, and thus literally starve the bacteria into surrender if present in sufficient concentration.

I have pointed out that since the 'nineties the trend of therapeutics had been towards applying Nature's own methods, and chemotherapy at first appeared a diversion in an entirely different direction. Now it is seen that sulphonamides act, as one may say, biologically, producing a deficiency disease in bacteria. In a sense earlier observations on salvarsan pointed to a similar conclusion, for just as the body can be educated by small doses of a toxin to resist larger doses, so the *Spirochaeta pallida* can become resistant to bigger doses of salvarsan if first given inadequate ones.

The multiplication of sulphonamide derivatives goes on apace, and already sulphapyridine has been displaced as first favourite, even against the pneumococcus, by sulphadiazine and sulphathiazole. I need not go into details beyond mentioning that, clearly, when a local action is required the less soluble forms are preferable; thus for dysentery sulphaguanidine is the drug of election.

The sulphonamides are not the only drugs to show bacteriostatic powers: gramicidin, for instance, is a crystalline polypeptide intensely toxic to pneumococci and haemolytic streptococci. The underlying principle is the same: to attach linkages to the main agent in such a way as to diminish its toxic and to increase its therapeutic effect. Thus salvarsan contains enough arsenic to be violently toxic if it had not been linked with certain organic groups. We have an instance of this in a drug which does not come within the present definition of chemotherapy; I mean salyrgan or, to give it the official name, mersalyl. It has long been known that mercury is toxic to the convoluted tubules of the kidney, and if given in sufficient strength can necrose them. Yet its organic compound mersalyl is used as a diuretic. Apparently it does so by throwing the absorptive power of the tubules out of action while allowing filtration to go on unhindered, with the result that a large quantity of dilute urine is passed. The toxic action of mercury has been greatly reduced, but it must be observed that it is still acting in a mild and selective way against the efficiency of the tubules to concentrate, and is thus a risky diuretic in kidney diseases.

The aim in chemotherapy may be said to be achieved when the toxic action of the drug is practically *nil* and its therapeutic effect is at the maximum. It is easy to prepare an antiseptic strong enough to destroy bacteria, but the tissues of the host would be damaged to a varying extent. Penicillin seems to have achieved the desired end of bacteriostasis without any such toxicity. It is only one of a whole series of such agents elaborated by micro-organisms and fungi, but is so far the best and most easily handled. By this time we have become familiarized with both its successes and its limitations. We know that its antibiotic power can be exercised in dilutions of one part in a million, and in its pure form even one in 50 millions. Like other chemotherapeutic agents, it differs from antiseptics in that it selectively attacks the organism causing the disease without doing serious injury to the tissues. We can now realize that, in malaria, quinine acts in exactly the way of a chemotherapeutic agent.

The discovery of penicillin by Fleming illustrates Pasteur's dictum that chance enters only the mind that is prepared. Many people, including Pasteur himself, must have seen their culture plates contaminated by moulds, but only Fleming saw the significance of the sterile ring surrounding the spot of contamination. However, just as it required Best to turn Banting's discovery of insulin to practical purposes, so have Florey's researches achieved this for Fleming's discovery.

The Endocrine Orchestra

To turn to an entirely different development of therapeutics: 12 years ago I delivered myself of the statement that the pituitary was the leader of the endocrine orchestra—a statement frequently repeated since. To-day I would add: and the hypothalamus is the conductor, for in the interval it has become clearer that the endocrine system is much more influenced by the nervous centres for emotional expression in the hypothalamus than was recognized 12 years ago. For an important part of this knowledge we are indebted to the anatomists. My analogy fails at one point, for in some ways the hypothalamus and the anterior pituitary form one unit, and diabetes insipidus, for instance, may result from a disorder of any part of it. But, changing the metaphor, we have in the pituitary a great transformer of nervous into chemical activity, which in its turn stimulates or inhibits other ductless glands by the appropriate trophic hormone. The hypothalamus in its turn receives impulses from the cortex, so that the psychic state can play on the endocrines through the pituitary, just as the endocrines can modify the psychic state. One has only to think of the influence of hyperthyroidism or hypogonadism to realize that it is not a one-way traffic between cortex, hypothalamus, and endocrines. This conception has greatly added to the interest in the treatment of mental states by physical means, which well accords with the prevalent psychosomatic view of disease in general. So the benefit of insulin-produced convulsions—accidentally discovered, I believe—fitted into the picture. Originally used for schizophrenia, they were soon replaced by electrically induced convulsions. The present view, I gather, is that insulin is still to be preferred for schizophrenia, but electricity for autonomous depression. The success of the latter is undoubted, but of the former more variable. And the electric method has far fewer unpleasant side-effects. It is difficult to see how the benefit is conferred, but it looks as if the violent convulsions may break down some resistances between association cells. Now that the surgeon is taking a hand and performing leucotomy, and is claiming successes, it would certainly appear that *something* at any rate is broken down. It is not surprising to learn that leucotomy is sometimes followed by a lack of initiative and tact, though intelligence and artistic capacity are claimed on occasion to be actually increased. It has been stated that the fundamental change is a diminution of self-consciousness, as if a pathological point in the cortex had been cut off from its mental connexions. To me it seems a desperate remedy, to be reserved for desperate cases.

Other physical methods in the treatment of psychoneuroses and psychoses include continued narcosis and partial loss of consciousness under light anaesthesia. The latter procedure is used for recovery of buried memories by hypnotic suggestion during the recovery period.

Psychological Aspects of Disease

But such methods are for the severest types of cases. The point which concerns all of us is the striking change from the materialistic outlook prevalent in my student days to the modern recognition of the psychological aspects of disease. On this let me quote Sir Francis Fraser, himself trained in the strictest sect of organic medicine. Speaking of the criticism that the medical schools give too scientific a training and send men out knowing next to nothing of the care of patients or of the personal side of practice, he says: "I am sure it is a just criticism, but maintain that hospital practice is not 'too scientific'—it is not sufficiently scientific. . . . Treatment based on the deduction that one patient's inefficiency is due to family troubles is just as scientific as that based on *x*-ray evidence of duodenal ulcer in another patient. To say 'there is nothing the matter' because the physical examination, *x*-ray evidence, and laboratory tests fail to disclose a cause of the trouble is, on the other hand, unscientific. If there was more exact knowledge of how the material and mental surroundings of our patients affect their functions and activities . . . clinical instruction would more nearly meet the needs of private practice, and it would be more scientific, not less."

This was written 10 years ago, and I am sure that the author would admit that since then it has been shown that the psychological factor plays a considerable part in the causation even of the organic lesion he selects—duodenal ulcer. And so the latest phase in the evolution of modern therapeutics is recognition of the psychosomatic factors in disease—thereby in a way completing the circle by a return to Aesculapius.

Discarded Methods

The path of this progress is littered on either side by discarded theories and practices. It is a chastening experience to turn over one's old case records. One suddenly realizes that some formerly favourite treatment has been completely forgotten. My belief is that we practise continually an almost unconscious revision, and in this way a consensus of opinion is reached: no one has openly attacked the treatment, perhaps—it has just passed silently into oblivion. And I suspect that a scrutiny of past literature from manufacturing firms would show that they have found it advisable to cease making a good many formerly vaunted remedies.

On this matter Trousseau's advice to his students remains as true as on the day when it was spoken: "Always use the new remedies while they still have power to heal." How is it that people were formerly cured by Bulgarian soured milk or by Bulgarian belladonna and are no longer? How is it that the routine use of vaccines therapeutically is fading out while their prophylactic use is increasing? One could quote many such examples. I think that admirable clinician the late T. A. Ross supplied the explanation. He noted that his experience of the result of the Weir Mitchell treatment fell into three periods. In the first the results were excellent and in the second variable; the third group was a failure. Then he realized that in the first he himself firmly believed in the method, in the second he had come to doubt it, while in the third he had ceased to believe in it and used it only at the request of others. I had the opportunity of studying Sir Lauder Brunton's methods fairly closely nearly 50 years ago. I attributed his undoubted therapeutic successes to two things—he had a genuine and deep sympathy for human suffering, and he always felt sure that he knew the precise remedy—preferably a new one from Germany—which would exactly suit the individual patient.

Conclusion

Well, I hope I have been able to show that gradually and by painstaking effort the profession has come into possession of a much larger number of well-attested remedies than formerly, in which we can have enough confidence ourselves justifiably to inspire confidence in our patients. We have a much clearer view of the fundamental principles of therapeutics, and the present position is full of promise for the future, for the last 40 years have shown greater advance than all the preceding centuries. We have passed away from the ancient mixture of empiricism and magic, by way of pharmacology, to a biological and indeed a biochemical approach. The tree of healing can now draw sustenance from many roots. In its present state it is still a young growth; let us see to it that its development is healthy, strong, pruned, and, above all things, honest.

SCABIES PROPHYLAXIS USING "TETMOSOL" SOAP

BY

KENNETH MELLANBY, Sc.D.

Recently I described (Mellanby, 1944a) some experiments in which attempts were made to control scabies infection. Except where therapeutic treatment with benzyl benzoate was given to all members of a closed community the results were disappointing. Since that paper was written a new method of some promise has been described (Davey *et al.*, 1944; Gordon *et al.*, 1944), and the present article describes a further prophylactic trial.

Prof. R. M. Gordon and his colleagues, in conjunction with Imperial Chemicals (Pharmaceuticals) Ltd. and Unilever Ltd., have produced a soap with good cosmetic properties which contains 10% of "tetmosol" (i.e., tetraethylthiuram monosulphide). The use of this soap has been shown to kill *Sarcoptes* and thus to cure scabies, though as a therapeutic agent at a treatment centre it is less efficient than benzyl benzoate. It is, however, so simple to use that it seemed possible that its general issue to an infected population would prevent further transmission of the disease. Whereas these authors described the therapeutic effect of tetmosol soap, they expressed the belief that its greatest value would be found in its use as a prophylactic against scabies—a property which they had already proved in the case of animals.

For a satisfactory test of the prophylactic value of tetmosol soap it was necessary to have a population showing a high incidence of scabies and to ensure that the soap was used by all individuals. Furthermore, facilities must be available for examining all subjects before and after the period during which the soap was used, in order to assess the effect on the incidence of scabies. Such conditions were found in a large mental hospital. Scabies was endemic among the patients; and the staff, having had many difficulties in combating the disease, were only too willing to co-operate in an experiment which might alleviate the position. To assess the amount of scabies present before, during, and after the experiment would obviously take a great many hours of skilled examination, but fortunately I had available at the Sorby Research Institute sufficient trained staff to make this practicable.

These facilities being available, I wished to place them at the disposal of Prof. Gordon. He decided, however, that he would prefer me to take the responsibility for the experiment, though he placed his advice at my disposal and also helped with the experiment in a number of ways.

Procedure

Before the experiment started every patient in the hospital was inspected; tetmosol soap was then supplied to approximately half of them. The details of the experiment were explained to the hospital staff, but nothing was said to the patients, who simply accepted the soap provided (it was rather pleasanter to use than that ordinarily available). All other treatment of scabies, whether in the control or in the experimental group, was discontinued for the 11 weeks of the trial.

Examination of the patients was carried out by volunteers from the Sorby Research Institute; these men had themselves had prolonged experimental infections with scabies, and were fully familiar with finding and removing acari. The examinations were all made under the supervision of Mr. W. C. Bartley. During the initial examinations I also was present, and during the latter part of the experiment Prof. Gordon and his colleagues visited the hospital on a number of occasions. The hands and wrists of all patients were carefully scrutinized, and any suspicious lesion was examined with a lens. Whenever any signs suggesting scabies were noticed but when no mites were found on the hands and wrists, the elbows were examined. A patient was said to have scabies only when a *live* mite was removed and demonstrated.

Results of the Experiment

The results of the examinations, before and after the use of tetmosol soap, are included in the accompanying Table.

Table showing the Therapeutic and Prophylactic Effects of the Use of 10% Tetmosol Soap and of Unmedicated Soap over a Period of 11 Weeks on the Incidence of Scabies in an Infected Community

Treatment	Total Patients	Observation Periods								
		Start of Experiment			After Six Weeks			After Eleven Weeks		
		Total Infected	Per cent. Infected	New Cases	Total Infected	Per cent. Infected	New Cases	Total Infected	Per cent. Infected	New Cases
Tetmosol soap 10%	705	93	13·2	—	9	1·3	—	9	1·3	—
Unmedicated soap	1,213	18	1·5	—	26	2·1	8	42	3·5	24

(*a*) *Preliminary Examination.*—Scabies was found to be much more common among the female than among the male patients; this agrees with the previous investigation (Mellanby, 1944b). Of the 1,101 women 106 (9.6%) had scabies; while an additional 41 (3.7%) showed some clinical signs of the disease but no live acari could be found—these cases were therefore omitted. The female patients lived in two separate blocks and in an admission hospital. For ease of administration and to ensure that only the right persons used the prescribed type of soap, one block containing 660 patients, of whom 89 (13.5%) had scabies, was issued with tetmosol soap for each individual, while the admission hospital and another block which contained 441 patients, of whom 17 (3.9%) had scabies, continued as before the experiment. The admission hospital had a varying population, and throughout the investigation no cases of scabies were found.

Only 5 of the 817 men (0.6%) were infected. Four of these cases occurred in one ward, which contained 45 patients, and the soap was issued here. The remaining 772 male patients (containing only one case of scabies) served as a control. The final arrangement, therefore, was that a total of 705 patients, of whom 93 (13.2%) were infected, were supplied with 10% tetmosol soap for their ablutions; while 1,213 patients, of whom 18 (1.5%) were infected, continued to use ordinary soap.

(*b*) *Examination After Six Weeks.*—As the table shows, after six weeks the situation was greatly altered. Among the 705 patients using tetmosol soap the incidence of scabies had decreased from 13.2 to 1.3%, and no new cases had occurred during this period; whereas in the control group, among 1,213 patients using ordinary soap, the incidence of scabies had increased from 1.5% to 2.1% and 8 new cases had been recorded.

(*c*) *Final Examination After Eleven Weeks.*—All the previous examinations were carefully carried out as described above, but for this final scrutiny particular care was taken to ensure that no cases were missed. Nine patients in the "tetmosol group" were found with scabies, none with heavy parasitic infections, and only three with mites on the hands. All of them showed signs of scabies at the original examination, made before the experiment started. Five of the nine cases (all with one or very few mites on the feet only) appeared clear at the six-weeks examination, but I believe that if the scope of the survey had allowed for a routine examination of other parts of the body on that date infection would have been discovered. Incidentally, three of these infected cases were bed patients who would have less access to the soap and whose feet might receive less lathering than the others. There were no new cases. A marked rise occurred in the control group, 3.5% of whom were now infected; the number of new cases had increased from 8 to 24 during the course of the experiment.

(*d*) *Sensitivity to Tetmosol Soap.*—Previous work (Gordon *et al.*, 1944) had shown that, while most individuals could use tetmosol soap for long periods without any harm to the skin, a small proportion of cases might find it irritating. Of the 705 patients originally issued with the soap three only, all of them women, appeared to be sensitive. Within a few days of starting to use the soap they developed an erythematous rash in the areas washed. These women were withdrawn from the experiment and the rash disappeared rapidly. No person developed a sensitivity after the prolonged use of the soap. None of the 45 men showed any sensitivity.

Discussion

These experiments show that tetmosol soap can act as a very efficient means of controlling scabies. It not only prevents the disease from spreading but also cures the majority of those who use it for a few weeks. There seems no doubt that its general employment would rapidly eliminate scabies from a community. Where efficient centres for treatment exist, and where it would prove difficult to enforce the use of medicated soap, benzyl benzoate is much to be preferred as a therapeutic agent, but there must be many parts of the world where tetmosol soap would have a wide field of application. It is obviously ideal for asylums and similar institutions; it would not be necessary for it to be used always, for an issue for a month or two each year (followed, the first year, by benzyl benzoate therapy for any few residual cases) would soon eliminate the disease.

The proportion of sensitive individuals unable to use tetmosol soap appears fortunately to be very small. They can be detected before any serious damage has been done to the skin, so there is little risk of causing dermatitis.

It may be noted that clothing and bedding were not disinfested in this experiment; the use of the soap alone successfully cured the majority of cases.

Summary

Patients in a mental hospital used tetmosol soap for a period of 11 weeks. Scabies, which was very prevalent at the start of the experiment, was almost entirely eliminated. Most cases were cured and the spread of the disease was prevented.

These experiments could not have been carried out but for the advice and co-operation of Prof. R. M. Gordon, Prof. T. H. Davey, and Mr. K. Unsworth. It is necessary to preserve the anonymity of the mental hospital concerned, but I wish to acknowledge that the success of the work was largely due to the help given by the medical superintendent and his staff. I am indebted to Mr. W. C. Bartley and to the men from the Sorby Research Institute for the care taken at the examinations. Also to Dr. H. A. Krebs, who had prior claim on the services of the volunteers during part of the period, for enabling them to continue with this work. The expenses of the investigation were met by the Medical Research Council, who also arranged for the supply of the soap through Imperial Chemicals (Pharmaceuticals) Ltd.

A circular issued by the Department of Health for Scotland announces that more beds are now available for civilians in Scottish hospitals. In future there will be fewer beds reserved for the emergency hospital scheme in voluntary hospitals and local authority general hospitals. This should help to remove the difficulties which hospitals have found in providing for the needs of the civilian population. "In view of the altered war situation, which has already led to substantial reductions in the general Civil Defence Services," the circular states, "the Secretary of State considers that it is now possible to meet current and estimated future requirements in hospitals for Service casualties and other patients within the scope of the emergency hospital scheme with a smaller number of beds than have been reserved formerly for the scheme." In future, hospitals will be authorized to admit to their reserved beds other civilian patients as well as those in urgent need of treatment, when the immediate requirements of the emergency scheme permit this to be done.

ARTIFICIAL INSEMINATION

BY

MARY BARTON, M.B., B.S.
First Assistant, Fertility Clinic, Royal Free Hospital

KENNETH WALKER, F.R.C.S.
Genito-urinary Surgeon, Royal Northern Hospital

AND

B. P. WIESNER, D.Sc.
Consulting Biologist, Royal Northern Hospital

The use of artificial insemination—i.e., the deposition of semen in the vagina, the cervical canal, or the uterus by instruments—has been discussed by several authors with personal experience of the method (Seguy and Vimeux, 1933 ; Lane-Roberts *et al.*, 1939 ; Cary, 1940 ; Green-Armytage, 1943 ; Guttmacher, 1942). We ourselves have used, and in certain respects developed, the technique of artificial insemination (A.I.) during the past five years. We can present but few conclusions in what must necessarily be a developing field, and cannot discuss the biological implications (e.g., determination of ovulation, frequency of male infecundity) of our observations in this interim report to clinicians. It is hoped, however, that it may serve to dispel certain misconceptions that are constantly arising.

Scope of Artificial Insemination

Impotence.—Many impotent husbands are capable of producing fecund semen by masturbation, and some impotent men regularly indulge in masturbation. Where treatment of impotence has failed, recourse to artificial insemination is indicated. Defects in the fecundity of the wife are first attended to. The physician then carries out an artificial *vaginal* insemination and Sims test (Barton and Wiesner, 1944) in order to determine the degree of cervical invasion by spermatozoa. Provided that invasion is adequate the wife is taught to carry out self-insemination within the fecund phase of the cycle (see below). The technique is as follows: She first douches with warm water (1 pint); half an hour later the husband passes semen into a cold dry glass container and allows it to liquefy at room temperature (about 10 minutes). The wife then draws up the semen into a clean dry urogenital glass syringe, and, lying on her back with knees drawn up, she passes the syringe into the vagina and very slowly expels the semen. The prone position should be retained for about half an hour. When teaching the patient it is important to demonstrate the distance to which the syringe may be inserted. The above procedure might suitably be employed in cases of hypospadias where insemination is superficial, but we have as yet had no such case under our care. Conception should occur readily. If it has not occurred within four or five cycles the case is reviewed. We have records of 11 selected cases. Eight pregnancies resulted in these. One ended in miscarriage ; the patient conceived again subsequently and the pregnancy is progressing. Five pregnancies went to term. One other continues at present.

Dyspareunia.—In some cases of incurable dyspareunia (e.g., those developing after injury or operation) artificial insemination may present the only means of obtaining pregnancy. In our opinion A.I. should not be used in any case of dyspareunia unless persistent attempts at cure have failed ; it should be remembered, however, that in some neurotics pregnancy itself may dispose of the disability. Vaginal self-insemination is the method of choice.

Failure to Ejaculate.—There are numerous cases, difficult to detect, in which the husband, though capable of penetration and sustained erection, either fails to ejaculate during intercourse or emits only a minute quantity of azoospermic fluid. In some of these cases ejaculation of fecund semen takes place during sleep. Where treatment has failed, the patient may be instructed to wear a washable condom during sleep, and the semen may be used for vaginal insemination, provided this is done immediately liquefaction has taken place.

Inadequate Cervical Invasion.—Sterility and reduced fertility are often associated with impaired cervical invasion by spermatozoa (Sims, 1868). Spermatozoa may be scarce in, or entirely absent from the cervical mucous plug, even though the sperm count and motility *in vitro* be high (Barton and Wiesner, 1944 ; Cary, 1940). We have found that spermatozoa which fail to invade the healthy cervical ovulatory mucus from the vaginal pool and are subject to rapid death in the vagina may under certain conditions survive for prolonged periods after transfer into the cervical canal. Furthermore, the occurrence of conception after deposition of asthenic spermatozoa in the cervical canal (first reported by Seguy) shows that the cervical mucus may maintain not only their motility but also their fertilizing capacity. The most critical task in the life of the asthenic spermatozoon appears to be penetration into the cervical mucus. No extended survival results from transfer into certain types of cervical mucus (e.g., those often seen in endocervicitis or in ovarian deficiency). Both experiment and clinical experience suggest that cervical insemination with the husband's semen (A.I.H.) should be used in cases of defective invasion, provided, first, that treatment of the male has failed to procure adequate invasive potency ; secondly, that the spermatozoa show good initial motility ; and, thirdly, that the cervical mucus during the ovulatory phase is clear and not gelatinous. More precise determinations (such as viscosity) can be made by *in-vitro* tests unsuitable for clinical routine. It should be added that impairment of invasion may be mechanical (e.g., malposition or abnormality of cervical passage), and some authors (e.g., Guttmacher, 1942) regard this condition as meriting artificial insemination.

Male Sterility and Other Indications for Artificial Insemination with Donated Semen (A.I.D.).—We have employed donated semen in a limited number of cases. In some of these (e.g., bilateral cryptorchidism, occlusion of ducts, fibrosis testis, incurable impairment of ejaculation) male sterility had to be regarded as permanent ; in some others (e.g., extreme oligozoospermia) a condition of severe subfecundity had failed to respond to treatment, so that chances of conception were remote. In two cases biological considerations were decisive. In one of them deafness had recurred in three successive generations of the husband's family ; in the other, transmissible nervous disease was established. Many other reasons have been advanced by patients requesting artificial insemination with donated semen (A.I.D.). Thus some couples, too impatient to submit to treatment, prefer the easy approach of A.I.D. This attitude is common in fecund women married to subfecund men. But quite often the husband is unwilling to undergo treatment, and the suggestion of A.I.D. comes from him. Some women demand A.I.D. without the knowledge of the infecund husband, claiming that paternity would save his self-esteem ; such women are usually good and devoted wives who, having longed for children for many years of marriage, have rejected other ways of becoming pregnant. Others are impelled by different motives: e.g., they plan to force marriage by what they consider to be a guiltless conception. Neither these nor other more dubious reasons have been accepted by us ; for while we do not feel in a position to suggest the general principles which should govern the application of A.I.D. we recognize the need for the greatest caution. In our work we have taken into account not only biological and medical factors but also the suitability of the couple for parenthood, so far as this can reasonably be estimated.

Procedure and Technique in A.I.H. and A.I.D.

Choice of Date

The wife is instructed how to record her rectal temperature throughout the menstrual cycle on waking ; for as a rule the variations of the temperature not only reflect the two phases of the cycle (follicular and luteal respectively) but also indicate clearly enough the approximate date of ovulation (see Chart). Any intelligent woman, once fully instructed, is capable of recognizing the ovulatory phase by the low level and/or the peculiar preluteal drop in the waking temperature. If this be indistinct in any cycle she should attend on the first day of the luteal rise. She is also asked to observe other signs of ovulation (Mittelschmerz, spotting, etc.). The final decision concerning the performance of insemination in any given cycle depends on the condition of the cervical plug, for if it is opaque the ovulatory phase is probably no longer, or not yet, in being. It should be borne in mind that even fecund women will occasionally have a cycle with indistinct ovulatory signs, and in less fecund women this may be more frequent.

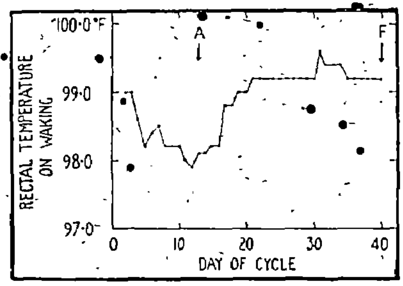

Chart of waking rectal temperature of an A.I.D. patient during only cycle under treatment. A: Day of artificial insemination. F: Day of positive Friedman test.

Insemination with Husband's Semen (A.I.H.)

We have found, in joint investigations with Dr. H. Coke (unpublished), that semen not infrequently carries pathogenic organisms which it would be unwise to deposit in the cervical canal. A bacteriological test is necessary in all doubtful cases (e.g., in sperm agglutination, pyospermia, haemospermia, etc.). Any infection should be attacked by local and systemic treatment of the husband. If these attempts fail the semen should not be used. Generally speaking, it is important to raise male fecundity to the highest possible level. Further procedure varies according to specific conditions. Where the main seminal deficiency consists in the lack of invasive power of a well-populated and viable semen the patients may be instructed to have intercourse half an hour after a thorough vaginal douche (warm water only). Semen may then be obtained from the posterior fornix within 60 minutes. The use of vaginal pools involves certain theoretical risks such as transfer of organisms from the vagina into the cervical canal. But some couples cannot adjust themselves to other methods of obtaining semen. The method is also valuable when it is undesirable, for psychological reasons, that the husband should be asked to masturbate repeatedly.

In cases of oligozoospermia and with semen of low viability masturbation specimens should be collected in suitable glass containers* just before insemination. The semen is used without additions and without any further manipulation except in cases of pronounced oligozoospermia, when it may be concentrated by gentle centrifugalization (approximately 500–1,000 revolutions per minute). In these cases the deposit is used with a small volume of supernatant fluid.

The patient is placed in the lithotomy position and the cervix, exposed by a dry unlubricated speculum, is swabbed with dry cotton-wool. A glass syringe fitted with an intra-uterine cannula or a special syringe of plated metal† is used, and a small quantity of semen (0.1–0.2 c.cm.) is drawn up into this syringe, which must be dry. As a result of certain still incomplete experiments we are under the impression that larger quantities of semen may impair the chances of intracervical survival of sperms. The tip of the cannula is passed into the cervical canal (1/4–1/3 in. of the external os). The semen is then injected *very slowly* into the canal. Most of the semen usually escapes from the cervix, but a small amount is retained. Forceful injection, recommended by Guttmacher (1942) and others, has neither an empirical nor a physiological basis; furthermore, it involves the risk of intra-uterine instillation. The patient may be allowed to leave a few minutes after insemination. Slight and passing discomfort sometimes follows cervical insemination; it is never severe, and may be disregarded.

It is an essential aspect of A.I.H. that it may have to be repeated frequently—i.e., *monthly* for a period of two years if necessary—before success is achieved or failure may be presumed. For the occurrence of conception is a matter of chance, though of high probability, even in fecund couples leading a normal married life. In infecund couples the chances are small even though A.I.H. be used, hence repeated "exposure to risk" is indicated.

A.I.D.: (1) Selection of Donors

So far as we know, no organized collection of semen for donation has ever been established, and the provision of semen is therefore entirely in the physician's hands. This inevitably involves considerable difficulty in obtaining suitable material. but has the advantage that the physician knows the donor individually. Certain facile assumptions suggested by purely biological considerations must be refuted. Thus the husband's brother might be regarded as the first choice because of genotypical resemblance; but experience shows that this choice is usually incompatible with secrecy, and that it is conducive to emotional disturbances involving both husband and wife. In fact, the prospective parents should never be aware of the identity of the donor. We have come to this conclusion as a result of disturbing observations in cases where the donor (though biologically approved by us) was chosen by the couple. It would seem that the responsible donor and the maternal woman are emotionally too deeply involved in procreation to regard their relationship with detachment. Now we carry anonymity to the point where the donor is never described to the patient save in most general terms which exclude identification; nor does the donor receive any specific information concerning the recipients. But if he wishes to limit his donation to certain types of parents his wishes are, of course, considered. In view of requests and suggestions made by medical men and others it should be emphasized that in our opinion no specimen of semen should be used for insemination except with the explicit agreement of the donor.

The principles which govern the choice of donors are designed to reduce obvious biological dangers. There must be no history of transmissible disease; the family history of the donor must be free of adverse characteristics of possible genetical significance, such as alcoholism, criminality, or tuberculosis. Excessively pronounced physical features are undesirable not only because they may be objectionable themselves. but also because they might facilitate identification of the donor.

Positive considerations concerning the eugenic quality of the donor's stock will largely be governed by the scientific views and perhaps the individual preferences of the physician concerned. Our choice has favoured men of intellectual attainments whose family history indicated that the members of at least two preceding generations were not only intelligent but also endowed with good capacity for social adjustment. Others might prefer donors characterized less by mental than by physical characteristics or achievements (athletes, etc.). In fact, we have hesitated before accepting cases for A.I.D. in which the interests of the parents were primarily athletic or sporting: and, speaking quite generally, the selection of donors with respect to the characters of the parents is a wide and complex problem. One has to bear in mind that the legal father may hope for a donated child with whose personality he might be in accord, and it must further be remembered that difficulties in the father–son relationship might be accentuated by the circumstances of A.I.D. Obviously, even the most careful choice of the donor for each case could not guarantee the desired characteristics, but it would increase the chances of matching parent and child. Present conditions make any such selection impossible.

The donor should have at least two legitimate children; this is of importance not only from obvious genetic considerations but also because his parental drive will have an available object. He must be of mature age (30 to 45), so that his character, viability, and other qualities can be properly assessed. His individual health should be adequate—primarily because it reflects constitutional characteristics. A certificate of the donor's physician is requested and a Wassermann test is carried out.

The fecundity of a donor must be reasonably high. The semen must have a volume of at least one c.cm., it must liquefy and rapidly become homogeneous, the sperm count must exceed 30 millions per c.cm., and there must be no spontaneous agglutination. Viability must be high—1% after 100 hours at 4° C. The spermatozoa must show little variation of head-lengths and include less than 15% abnormal forms. Indifferent or intermediate and pathological cell-forms (e.g., di Biasi cells) must be rare. The bacteriological cultures obtained from the fresh semen must be sterile or show but a light growth of harmless contaminants such as *Staph. aureus* and diphtheroids. These requirements are dictated not only by the desirability of a high conception rate but also by the need to reduce the risks of miscarriage. Periodic checks upon the seminal conditions, etc., are made.

---

* Semen-containers and syringes should be cleaned without the addition of the usual antiseptics. They must be thoroughly dried before use.

† Supplied by A. J. Travis to our design.

The donor's blood group should be identical with that of one parent if it is desirable to minimize the possibility of bastardization. The parents usually desire donors of like race—e.g., Jewish couples usually ask for a Jewish donor. On the other hand, it is a curious reflection on the present epoch that some have specifically asked for non-Jewish donors, since they want to safeguard the child so far as is possible against anti-Semitism.

The greatest difficulties in A.I.D. arise from the fact that to most balanced men the task of donation is unpleasant, and because of the low fecundity of most mature men. Hence but a very small panel of donors has been established so far. Fortunately, the number required at any given time is not great. For while a specimen of semen should not be used for more than a few hours after emission, it can during this period be utilized for at least 20 inseminations. In theory the number of possible conceptions from one specimen is very much higher, for we have satisfied ourselves that a single insemination with 0.01 c.cm. of semen may suffice to procure pregnancy. It follows that a fecund donor submitting two specimens weekly could, with ideal conditions, produce 400 children weekly (that is, about 20,000 annually).

A series of systematic observations has shown that A.I.D. has a good chance of success on any one of three cycle days—viz., on the day of the minimum waking temperature, on the day preceding it, and on the first day of the rise. Thus the general organization of A.I.D. requires an arrangement by which fresh semen is delivered to the laboratory two or three times weekly, while the recipients are asked to attend at the corresponding hours during the presumptive ovulatory phase. But while a small panel of donors can serve the immediate purpose, it seems desirable to limit the number of children any one donor should be allowed to have, lest the risk of marriage between sibs not known to each other should assume dangerous proportions. For this reason we have set an arbitrary limit of 100 children for each donor—not yet attained by any one donor.

The instructions given to a donor are simple, and are mostly concerned with delivery of the semen in a fresh condition without contamination. A sterile glass-stoppered container is supplied by the laboratory, and the specimen is maintained at room temperature. Donated semen is used for cervical insemination as described previously for A.I.H.

A.I.D.: (2) Preparation of Parents

A couple accepted for A.I.D. are made clearly aware of its biological, legal, and other implications and difficulties. Most couples have preconceived views concerning the method. Apart from believing that a single insemination on an arbitrary date is all that is required, they also assume that the husband can be nearly reproduced by a specially chosen donor. Hence they must be told that no likeness, physical or otherwise, can be guaranteed. The explanation of potential legal complications is based, in the absence of precedent, on counsel's opinion, for which we are indebted to our legal advisers. It is emphasized that the husband might change his attitude in years to come and attempt to disown the child. Both the possibilities and the difficulties of such attempts are pointed out. The couple are further informed that the child will be legitimate if the husband is registered as the father. Such registration is demanded although it constitutes an offence. For purely formal protection of the physician a written request for A.I.D., signed by husband and wife in the presence of the physician, may be obtained. This is filed under seal, and arrangements are made for the destruction of the document at the physician's death. The prolonged consultation required at this stage provides an opportunity to impress the couple once more with the significance of their decision; and the physician can assure himself that the husband is not either acting on the spur of an ill-considered decision or submitting half-heartedly to his wife's request. On this as on other occasions an attempt must be made to establish the mutual confidence between patients and physician which is needed for their relationship and which is more important than any formal legal safeguard; the latter, in any case, could not cope with the numerous human complications which might arise in this field. Lastly, the patients are assured that complete secrecy will be observed.

Dangers

1. In our experience no dangers attach to the actual process of cervical insemination provided that no air is injected and no semen is allowed to enter the uterine cavity. But dangers may arise from the use of semen infected with pathogenic organisms, and while it seems that the healthy cervix is endowed with a defence mechanism against some semen-borne organisms it is not possible to detect impairments of cervical defence. At this point it may be remarked that we originally employed intra-uterine insemination as suggested by various authors. But on discovering the high incidence of seminal infection we abandoned this often painful procedure, which in the hands of an American author has resulted in grave injury (pelvic abscess and permanent subfecundity) (Bickers, 1944).

2. The question of dysgenic conception from the use of subfecund semen has often been raised—not only in the literature but also by patients who fear that the predominance of abnormal or asthenic sperms may be reflected in the constitution of the child. Now, this is indeed one of the most difficult problems in all animal-breeding, and yet one which has scarcely been formulated precisely—much less solved conclusively. It must be remembered that deliberate (experimental) damage to animal spermatozoa may not prevent conception but may result in non-viable zygotes, and that, in man, exposure of the father to some poisons has been stated to affect the offspring (Hamilton, 1925; DeLee, 1924). In human reproduction a close association of high miscarriage rate with semen of low fecundity has been claimed, and this association is indeed a common experience in the therapy of sterility: threatened miscarriage, usually at the end of the third month, occurs in more than one-third of the women who have conceived from subfecund semen. Cervical insemination might increase the incidence of non-viable progeny by interfering with the mechanism of cervical selection, which inhibits the invasion of the cervix by abnormal spermatozoa. In artificial insemination the cervix receives many abnormal spermatozoa which could not invade under their own power. Much more experience must accumulate before the standard of the progeny of subfecund parents can be assessed properly. But it is encouraging that normal and viable infants were born in all our cases of A.I.H. in which pregnancy went to term without accidents of parturition or gestation. Also, the frequency of tubal pregnancy and other abnormalities of gestation was no greater than might be expected in a corresponding group of unaided conceptions.

3. A potential danger arises from the tempting chance of experiments with semen. Human sperms die fairly rapidly unless specific media are employed which can be used for storing semen. Again, infected semen can be disinfected without visibly affecting the sperms. Such procedures might simplify the task of artificial insemination, but we feel that interference with the semen carries the risk of affecting the progeny—a risk which may safely be accepted in animal-breeding but never, in our opinion, in human reproduction. Non-interference with semen should be carried to the point where storage or transport over long distances (which has been successfully used in America) is avoided. Artificial insemination should follow the natural course of events as closely as possible, and perhaps even centrifugalization should be regarded with reserve.

4. Lastly, there is always the danger of psychological damage to the patients, both husband and wife—e.g., either through the inevitable interference with their sexual relations or through the consciousness of reproductive inferiority. Careful initial selection of cases and attention to the patients' reactions can reduce this risk.

Results

For a variety of reasons no useful statistical analysis of the results of A.I. can yet be presented. The method and technique of A.I. have changed much during recent years—e.g., through the systematic use of the temperature chart—and the selection of cases has tended to become more stringent; the number of inseminations carried out before abandoning a case has increased, and so on. Hence results of earlier series are of little significance. Furthermore, in assessing the results of any given group, such factors as the age of the wife, the degree of male fecundity, etc., must be taken into consideration, and these vary greatly. The primary factor, however, is represented by the assessment of the case. Cases can be so selected that

A.I.H. will be successful in most, or in hardly any case, and the same applies to A.I.D. A few illustrations are given below:

1. *A.I.H.*—In a recent series of 30 successive cases A.I.H. was carried out because of low invasive power of the semen. In addition, spermatozoal density was low (less than 10 millions per c.cm.) in six cases; and more than 15% abnormal head forms were present in the semen of five cases. Female infecundity factors—e.g., impaired tubal function, infrequent ovulation, etc.—were detected or strongly suspected in six cases. Insemination was carried out in at least four successive cycles where necessary and, as a rule, more than once in each cycle. One case is counted twice, for the patient miscarried after the first series of inseminations, and then made a second attempt. Nine conceptions occurred—in one case during the first cycle, in the others in the third or fourth cycle. Four pregnancies terminated in miscarriage in the fourth month of pregnancy or earlier; four others resulted in the birth of a viable infant. In the last case the pregnancy continues at the time of writing. In 21 cases no conception was recorded with certainty, but two conceptions may have occurred (? early miscarriage). The negative cases are characterized by a higher average age of the wives, but not by a higher frequency or greater severity of manifest infecundity factors in either husband or wife.

2. *A.I.D.*—A recent series of 15 successive cases in which donor M. was employed consisted of women in whom no serious infecundity factor was discovered, though four of them were 40 years of age or over. Insemination was repeated where necessary in at least six cycles. Conception resulted in 10 cases. The negative cases were represented by one woman in whom insemination was repeated during eight cycles and then abandoned, and the women aged 40 years or over. The fate of the 10 pregnancies varied. One was tubal and had to be terminated; one ended in miscarriage (end of the second month); five went to term uneventfully or are nearing term at present; and three terminated successfully at 45 weeks. The number of cycles during which inseminations were carried out in the positive cases varied from one to seven. It may be said that, in our experience, repeated A.I.D. is nearly always successful in reasonably young women in whom infecundity factors have not been detected. The infants produced by donor M. in this as in another series show no abnormality and are progressing favourably. Their physical types vary widely, and the parents state in every case that they are glad to have availed themselves of this service.

Summary

In some cases of male impotence, dyspareunia, ejaculatory failure, and defective cervical invasion, artificial insemination with the husband's semen may be indicated. In the first three conditions named, self-insemination by the wife is possible.

Artificial insemination with donated semen has been carried out in cases of incurable male sterility and for genetic reasons.

The procedure and technique of artificial insemination with the husband's semen and artificial insemination with donated semen (choice of cycle day, suitability of semen, method of cervical instillation) are described.

The selection of semen donors and the organization of artificial insemination with donated semen are discussed.

Some potential dangers of artificial insemination—e.g., uterine infection, dysgenic conception from defective or damaged sperms—are enumerated.

Two small series of cases are reviewed.

A search for methods of controlling Scotland's "plague of midges" will be the task of a small committee of Scottish scientists headed by Brig. F. A. E. Crew, professor of public health and social medicine at Edinburgh University, and director of biological research at the War Office. Mr. Thomas Johnston, Secretary of State for Scotland, invited the committee to consider whether measures similar to those used in the Army against mosquitoes and other insect pests dangerous to health could usefully be employed against midges and other biting flies. The committee's first step will be to review what is known about methods of attack on insects and their breeding grounds and to advise whether these methods can be used or can be modified for use against midges.

METHYL BROMIDE POISONING

EFFECTS ON THE NERVOUS SYSTEM

BY

A. BARHAM CARTER, M.D., M.R.C.P., D.P.M.
Physician to Staines County Hospital

Methyl bromide (CH_3Br), a non-inflammable colourless gas at ordinary temperatures and pressures, fairly easily compressible into liquid form, is used extensively as an insecticide, fire extinguisher, fumigant, and refrigerant. It is known to be toxic to man in various ways, and as it is without smell in low concentrations and is 3.3 times as heavy as air it constitutes a very real industrial hazard. The toxic effects described in the literature are: (1) on the skin, giving rise to a vesicular irritative dermatitis and second-degree burns; (2) on the respiratory system, producing bronchitis, bronchopneumonia, pulmonary congestion and oedema; (3) on the alimentary system, with gastro-intestinal upset and hepatic dysfunction; (4) on the nervous system, with both an acute and a chronic symptomatology. It is with the last that this paper deals, and although references show a familiarity with other manifestations, no attempt has been made to evaluate or define the more chronic effects on the central nervous system.

Review of Literature

Heiman (1944) has given a full review of the literature (chiefly Continental) concerning the general toxic effects of methyl bromide on man. An analysis of cases describing the acute neuropathies produced by short exposure to high concentrations shows in the majority a prodromal stage of headache, dizziness, nausea, vomiting, and generalized weakness with transient diplopia and amblyopia, followed by a period of mental excitement with focal or generalized epileptiform convulsions, muscular tremors and spasms, mental confusion, psychomotor acceleration, and restlessness, amounting at times to acute mania. This stage is accompanied by fever and occasionally cyanosis with methaemoglobinaemia, and in fatal cases is followed by coma, increase in muscular spasms, and convulsive seizures with death in hyperpyrexia.

If the patient survives, there follows a long period of convalescence, lasting up to 18 months in a few cases, in which the epileptiform attacks become less frequent, the mental confusion and excitement gradually abate, and visual disturbances slowly improve, although nystagmus and sluggishly reacting dilated pupils persist, with mental depression and insomnia. Morbid hunger has also been described in this connexion.

Pathological material confirms the involvement of the brain and meninges in the acute type of case, but no reference is made to the spinal cord or peripheral nerves. Glaser (1928) described oedema of the brain with no further details. Goldschmid and Kuhn (1920) found degeneration of the cortical cells in the cerebral hemispheres, particularly in the frontal and parietal lobes. Duvoir (*et al.*, 1937; 1939) found acute congestion of the brain and meninges, and Heiman decrease of cerebrospinal fluid, swelling of the brain with engorgement of pial veins but no haemorrhages. The brain was found to contain traces of methyl alcohol and formaldehyde, and 62 mg. of bromide in 300 g. of tissue. No microscopical findings were mentioned.

The neurological effects of long-continued exposure to small concentrations have been described in only a few cases, and no pathological material is available, except from animal experiments. Jacquet reported one case with vertigo, weakness, transient diplopia, and dimness of vision following brief exposure, and two cases with similar symptoms plus flaccid paralysis of legs and psychic disturbances after more prolonged exposure to an unknown concentration. Watrous (1942) much later reported the occurrence of mild nervous symptoms in 31 persons out of a total of 90 working in a filling-and-sealing room of a methyl bromide plant who were exposed for two weeks to a concentration of less than 35 parts per million. Headache, vertigo, difficulty in focusing, muscular pains, and dimness of vision were the symptoms observed, but no neurological abnormalities were found on examination. All these cleared up within two months of the patients' leaving the factory.

De Jong (1944) has reported three cases with involvement of the central nervous system who were exposed to methyl bromide vapour in low concentrations for an average of six months before the onset of symptoms. One of these patients had a history of numerous methyl bromide blisters on his hands. The nervous symptoms in these cases were vertigo, unsteadiness, and blurring of vision, followed by diplopia, weakness, numbness and tingling of the legs, unsteadiness of gait, and headache. No psychic disturbances were observed. Examination revealed moderate dilatation of pupils, with nystagmus, some cerebellar ataxia of the limbs, exaggerated tendon reflexes, and Babinski response in one case; diminished ankle-jerks in one case; normal abdominal and cremasteric reflexes, diminution of vibration sense in both legs with retention of position sense, and diminished cutaneous sense peripherally in one case. The C.S.F. was normal in each instance, not under pressure. Blood counts were normal, and the blood bromide varied from 9 to 13 mg. of sodium bromide per 100 c.cm. All the cases showed slow improvement over three months.

Meadows, in a personal communication, describes the case of a man aged 36—employed in the same factory as the case described below in detail—who had been working with methyl bromide for two months when he began to complain of numbness and tingling of both hands and feet, with progressive weakness of the legs. This was followed by dimness of vision, with inability to read near print, and peeling of hands and feet. On examination visual acuity was impaired, nystagmus was present, there was weakness but no wasting in the lower limbs, ankle-jerks were absent, and the left plantar was doubtful. There was loss of vibration sense in the legs, but no other sensory changes. Investigations of blood and C.S.F. were negative. The condition improved, and the patient was advised not to return to his work. It is only fair to add that at this time (a year ago) investigations failed to reveal any leakage of the gas, but when a further case arose a leakage was found in the department dealing with insufficiently filled extinguishers requiring reopening and refilling.

Animal experiments are interesting. Four investigators in America exposed rats, rabbits, guinea-pigs, and monkeys to varying concentrations of methyl bromide for varying times. The particular experiments appertaining to chronic neurological effects showed that 14 to 46 exposures to concentrations of 0.25 mg. per litre produced paralysis of a flaccid type in the limbs of rabbits and rhesus monkeys: these paralyses were bilateral, and affected equally the front and hind legs of the rabbits but chiefly the legs of the monkeys. On discontinuing the exposures when these paralyses had developed, the monkeys showed loss of equilibrium with a general ataxia of movement suggesting to the experimenters a cerebellar involvement. The reflexes became normal when the function of the limbs returned. Exposures to concentrations of 0.13 mg. per litre produced paralyses in rabbits, but had no effect on monkeys. Careful histological examination of the brain and spinal cord in the affected animals showed no abnormalities, but no mention is made of examination of the peripheral nerves.

Illustrative Case History

A male aged 17 was admitted to Staines County Hospital with the history that he had worked at a methyl-bromide-producing factory for 18 months, but had changed his type of employment a year later. During the six months before admission he had worked in the refilling department, where fire extinguishers which had been insufficiently filled were reopened and refilled with methyl bromide until they had attained the standard weight. He and the other employees in this department realized that a certain amount of gas escaped, but there appeared usually to be sufficient extraction by ventilation. The more efficient the workman the less the escape of gas. The patient was always rather clumsy, and the employees remarked on the increase of escaping gas in his work. On questioning, it was stated that the gas had a peculiar stale odour, "as though the air had not been changed for a fortnight" (this is contrary to the general belief that the gas is odourless).

Two months before admission the patient began to notice weakness of his legs, interfering with his ability to jump on chairs, buses, etc.; at the same time he felt his toes tingling and found difficulty in forming his words. His mates remarked that "he was more stupid than usual," and he developed a methyl bromide dermatitis and burns on his hands. At no time did he complain of his symptoms to the factory doctor, who examined the employees carefully each week. One month later he found that his hands were clumsy and that he was much slower in his work and unable to run owing to weakness of the legs. He had difficulty in going up and down stairs, and began to notice he was seeing double. There were no further pains or any dysaesthesiae. Three weeks later—a week before admission—he was unable to read or see things close to him, and his speech was becoming worse, although his unsteadiness of hands was stationary. On the day of admission he was hardly able to walk to work; he complained of constant double vision, giddiness, and weakness, and when he got to his job he fell down and was quite unable to get up. He said his head ached and "he couldn't see his feet." Many of his symptoms had been noticed by his fellow employees, although they had experienced none of them, and these were ascribed to his unhappy home life with a cruel stepfather. On inquiry the home life of the boy was found to be unsatisfactory, but no overt cruelty seemed likely and his diet appeared to be adequate. He had no history of sore throat.

On admission he was mildly confused, with a considerable slurring ataxic dysarthria, and was unable to stand or walk, owing to weakness of his legs. His confusion was chiefly a disorientation in time, and it was impossible to elicit any chronological history from him He was somewhat dull and retarded, but no other psychic abnormalities were found. Pulse and temperature were normal, and the only abnormal signs were found in the nervous system. His pupils were dilated, with good reaction to light but less to convergence-accommodation: he was unable to read, but had 6/9 vision in both eyes at 6 metres. Visual fields were full to confrontation, and his disks were normal. He had lateral nystagmus, and a fine rotatory nystagmus in both eyes on looking up, with diplopia at extremes of lateral movement. The upper limbs were of normal tone, without weakness, and showed diminished tendon reflexes. Slight motor incoordination was present and he was unable to perform rapid repetitive movements. There was no sensory loss. The abdominal reflexes were greatly increased and cremasterics normal. In the lower limbs undue flaccidity with marked motor weakness at all joints was observed, and the knee-jerks were just present, although the ankle-jerks could not be obtained. Motor ataxia in both legs was very obvious, and the left plantar response was Babinski. Vibration sense was absent in both legs up to the knees, and there was poor appreciation of position on the right. No superficial sensory changes were found. There was precipitancy of micturition. Lumbar puncture was performed and a clear freely communicating fluid obtained at a pressure of 100 mm. of water.

Two days after admission he began to be able to read and could move his legs about in the bed without trouble; his hands had lost their ataxia. A week after admission he showed nystagmus, ataxic dysarthria, and a broad-based staggering gait, with generalized reduction of tendon reflexes and diminished vibration sense in both legs His plantars were now flexor, and he could focus normally without diplopia. The picture was very reminiscent of hydantoinate (epanutin) intoxication. The patient's condition slowly improved and he was fit for physiotherapeutic re-educational exercises a month after admission, by which time he had a slightly slurred speech, some difficulty in turning and walking fast, and nystagmus. All other abnormalities had cleared.

Seven weeks after admission he was discharged with no residual sequelae, and was advised not to return to employment where methyl bromide was used.

Investigations.—Cerebrospinal fluid:—Protein, 40 mg. per 100 c.cm.; 4 lymphocytes per c.mm.; chlorides, 640 mg. per 100 c.cm.: bromide (sodium), 27 mg. per 100 c.cm.; W.R. negative; Lange gold curve, 0000000000. Blood count:—Red cells, 4,850,000: haemoglobin, 90%; white cells, 9,000—polymorphs 70%, lymphocytes 26%, monocytes 2%, eosinophils 2%. The urine showed no abnormality.

Discussion

In exactly half the cases of methyl bromide poisoning described in the literature (39 out of 78) subacute or chronic effects on the nervous system have appeared, and in addition animal experiments confirm this type of damage from prolonged exposure to small concentrations of the gas. The neurological signs divide themselves into central and peripheral effects, and the latter seem more important in the chronic cases. These appear to be the result of a toxic peripheral neuritis with numbness, tinglings, flaccid pareses, loss of reflexes, and few sensory changes except loss to vibration. In some cases there was muscular wasting with complete paralysis, although no increase in protein or cells was found at any time in the cerebrospinal fluid.

The central effects described comprise headache, transient diplopia, difficulty in accommodation, dimness of vision, dysarthria, generalized incoordination, and vertigo. In four cases only, with prolonged exposure, psychic disturbances appeared.

showing retardation of thought, drowsiness, mild disorientation, and slow response to questioning. Objective signs were present in 10 cases of this type, and included nystagmus, pupillary dilatation with sluggish reflexes to light, diminution of vision, cerebellar ataxia and dysarthria, and loss of vibration and position sense. Centrally, therefore, the main incidence seems to be on the optic nerves, oculomotor nerves, cerebellar connexions, and posterior columns, with occasional involvement of the higher centres producing psychic disturbances.

Treatment up to the present has been only symptomatic, as these cases improve with rest in bed and removal from exposure to the gas, and no great increase in blood or cerebrospinal fluid bromide has been found (up to 27 mg. of sodium bromide per 100 c.cm.). It is presumably the methyl combination that does the damage, as bromide poisoning is not clinically apparent until blood concentrations of above 100 mg. per 100 c.cm. are reached.

Convalescence is prolonged, with persistence of some ataxia, undue fatigue, and nystagmus long after the disappearance of the peripheral neuritis, but most of the cases seem to have recovered within a year. Two patients were returned to employment where the risk of exposure to methyl bromide was still present, and both relapsed within six months and had lost time from work owing to residual and recrudescing symptoms.

Summary

The effects of chronic methyl bromide poisoning on the nervous system are described, with a review of the literature and an illustrative case history.

These effects, on analysis, form a pattern of dysfunction mainly affecting the peripheral and optic nerves, cerebellar connexions, and certain spinal cord tracts, although the material available is not sufficient to postulate a definite syndrome associated with methyl bromide poisoning.

On removal of the patient from the toxic hazard the symptoms slowly clear up without any specific treatment and apparently without permanent sequelae, but it is inadvisable to allow return to further exposure.

HYPOPROTEINAEMIA DURING RECOVERY FROM SEVERE ANAEMIA

BY

TREVOR DAVIES, M.R.C.S., L.R.C.P.
Resident Medical Officer, Wrexham and East Denbighshire War Memorial Hospital

Generalized oedema due to diminution of the serum proteins is not a common complication of the treatment of anaemia and does not occur unless the ingestion of protein is low during the period of regeneration of haemoglobin. It is not generally recognized that the formation of haemoglobin makes great demands upon the protein reserves of the body. Heath and Taylor (1936) state that for a gain of each 10% of haemoglobin about 80 g. of protein is required and that haemoglobin formation is accompanied by a positive nitrogen balance only when the diet contains more than 6.2 g. of nitrogen a day. They say, however, that haemoglobin formation takes place at a normal rate even in the face of a negative nitrogen balance, and that in these circumstances the demand for nitrogen for haemoglobin formation appears to be supplied by tissue and plasma proteins.

The case described below is one of severe nutritional oedema following the treatment of pernicious anaemia. Faulty dietetic habits had been present for years, and they were not fully corrected during the period in hospital preceding the onset of the oedema.

Case Report

The patient, a married woman aged 49, was admitted to hospital on June 13, 1944. She complained of increasing lassitude and loss of weight over a period of a few years. She stated that she had lost about 4 st. in the past 18 months. She had suffered from dyspepsia most of her life, and often vomited if her food "disagreed" with her. Her appetite had become very poor, and she existed mainly on a soft carbohydrate diet, rarely eating meat. She had had occasional diarrhoea during the past four years. The climacteric occurred early in 1944. There was no history of any previous severe illness.

On examination the patient was very emaciated and pale. The skin had a faint yellowish tint, but she had a malar flush. Her hair was thin and lustreless, and her general appearance suggested a mild degree of pituitary cachexia rather than pernicious anaemia. The tongue showed slight atrophic glossitis, but there was no koilonychia. She had a tachycardia of 100 a minute, but the pulse was regular and of good volume. B.P. 120/75. The heart was slightly enlarged, but there were no murmurs. Examination of the chest revealed no abnormality, and there were no abnormal neurological signs.

A blood count revealed a macrocytic anaemia. Red cells, 1,600,000 per c.mm.; Hb, 35%; C.I., 1.13; white cells, 7,500 per c.mm. A fractional test meal showed complete achlorhydria. A glucose-tolerance test gave normal figures, and the Wassermann reaction was negative. Radiological examination of the alimentary tract by barium meal and enema revealed no abnormality.

Treatment with liver extract, ferrous sulphate, and vitamin B complex was begun, and the haemoglobin and red cells increased steadily, with a maximum reticulocyte response of 10%. On July 7 a painful thrombophlebitis occurred in the left saphenous vein, and a week later a similar condition occurred in the right saphenous, both accompanied by oedema of the leg. The inflammation and oedema subsided quickly, however. On Aug. 9 the haemoglobin was 76% and the red cells 3,700,000 per c.mm. The patient felt very much better and lost her feeling of lassitude, but she could not be induced to eat the full hospital diet. She constantly refused meat, but ate moderate quantities of carbohydrate foods. On Aug. 11 gross oedema of the legs, abdominal wall, and trunk appeared, almost overnight. Ascites was present; but the oedema of the trunk finished abruptly at the mid-dorsal level—none was seen in the arms or face. There was no pain or pyrexia and the urine was normal. No pleural effusions were present, but moist sounds were heard at both lung bases. The urinary output was small (15 oz. in 24 hours). The serum proteins were low: total protein, 4.16 g. per 100 c.cm. (albumin 1.8%, globulin 2.36%); serum sodium, 346 mg. per 100 c.cm.

On Aug. 16, 80 g. of protein in the form of reconstituted plasma was given intravenously by slow drip and the patient was persuaded to eat a high-protein diet. Almost immediately a marked diuresis resulted, the urinary output often exceeding 80 oz. a day during the next three weeks, during which time the oedema almost completely disappeared. On Aug. 20 the total serum proteins had risen to 5.25%, the diuresis was still being maintained, and the oedema was steadily diminishing. On Sept. 8 the patient was out of bed and felt quite well. Very slight oedema of the feet was present, but this was probably attributable to the thrombophlebitis. The serum proteins at this date were: total protein, 5.61% (albumin 3.36%, globulin 2.25%). The liver treatment was maintained and the haemoglobin had risen to 80%. She was discharged from hospital on Sept. 23.

Comment

The above case illustrates the importance, during the treatment of severe anaemias, of maintaining a diet rich in protein so as to provide the excess of protein necessary for haemoglobin regeneration. If protein intake is inadequate the depletion of the reserves of stored protein may not become evident until a considerable amount of haemoglobin has been formed. As stated before, in order to prevent this depletion a daily intake of more than 6.2 g. of nitrogen available for protein formation is necessary. Inadequate intake of nitrogen owing to a psychological distaste for food appears to have been the main factor in the causation of the protein deficiency in this case, but it is interesting to speculate that the fatty degeneration of the liver which occurs in pernicious anaemia may have impaired the hepatic synthesis of tissue protein and that the hypoproteinaemia may to some extent have been "hepatic" as well as "prehepatic."

The treatment of clinically severe states of hypoproteinaemia with gross oedema is a matter of some urgency. When the deficiency is of the "prehepatic" type, due to inadequate alimentary intake of protein, it is an advantage to supplement an increase in orally administered protein by parenteral therapy. The transfusion of plasma is a convenient method. It was used with success by Holmes (1944) in a similar case of hypoproteinaemia following the treatment of a microcytic anaemia in a vegetarian. Large amounts of plasma may be needed to treat severe protein depletion. The actual amount used in a given case must be judged by the clinical response in the form of diuresis and reduction of oedema. In this case and in Holmes's a moderate amount of plasma was given intravenously to initiate diuresis, and the complete restoration of protein was obtained by an increase in the oral intake.

Recently the intravenous infusion of amino-acids has been suggested by several American workers (Elman, 1940; Shohl *et al.*, 1939; Farr and MacFadyen, 1939; Brunschwig, Clark, and Corbin, 1942). The material used was a hydrolysate of casein; but this is difficult to prepare in a state suitable for intravenous infusion, and unpleasant reactions are said to occur. In "prehepatic" types of hypoproteinaemia the intravenous infusion of amino-acids would appear to have no clinical advantages over plasma transfusion. If plasma is not available whole blood could be used. The casein hydrolysate containing essential amino-acids should be a useful preparation for oral administration, however, particularly in nutritional deficiency of psychological origin.

I wish to thank Dr. J. MacD. Holmes for permission to publish this report and for his advice and criticism.

Medical Memoranda

Gastric Drip Infusion to Combat Dehydration in Infants

In the treatment of neonatal sepsis the outlook is at present largely determined by whether or not the causative organism is sulphonamide-sensitive; whereas in future it will be a question of whether or not it is penicillin-sensitive. But besides this there will always remain the problem of how to relieve the dehydration.

Of the methods at present in common use each has its drawbacks. It is rarely possible to administer enough fluid by the subcutaneous route to overcome the dehydration in a seriously ill infant; besides which there is the danger of introducing another portal of entry of sepsis. The intraperitoneal route is inclined to be accompanied by considerable shock to the baby and is not without risk. The rectal route is usually impracticable owing to diarrhoea. By the intramedullary and intravenous routes it is always possible to give enough fluid; but unfortunately it is all too easy to give too much. This is especially so in babies, where the kidney and heart can be so easily overloaded and where pneumonia is so great a danger. Unfortunate accidents with the intramedullary method have been recorded, therefore we always attempt an intravenous drip first; and though it is fairly rare to be unable to get an intravenous drip running it is a difficult and time-consuming procedure.

In view of all these objections we began in August of this year to try the effect of a continuous drip into the stomach or the lower end of the oesophagus. It is neither an original nor a new technique, but having found it most successful we suggest that it should be more widely known and used in overcoming dehydration. We found that it was easily possible to give to a neonatal baby up to forty ounces of fluid in the day. On the other hand, compared with the intravenous route, the danger of overloading the circulation is greatly diminished. Another advantage is that it is a means of enteral medication and of gradually changing the composition of the fluid. The technique is simple, and a gastric drip can be erected in a few minutes by a competent nurse.

At present our routine is as follows. In any case in which there is severe dehydration a gastric drip is erected. If there has been much vomiting sterile water or normal saline is given in the first instance, and then this is replaced by albuminous fluids such as "secway" or egg-white. It is usually possible to relieve dehydration in one day, but if necessary the drip can be left *in situ* for much longer, provided that the tube is removed every twenty-four hours and the whole apparatus resterilized. The flask, clip, rubber tubing, and drip chamber are the same as for blood transfusion, the rubber tubing being joined to a fine (No. 5) rubber catheter by a glass connexion. The tube is passed through the nose, as we find this less irritating to the baby. It is kept in the required position with strapping on the forehead. The infusion fluid is warmed before placing in the flask and is kept warm by running the tube over a hot-water bottle, which requires frequent changing.

While originally introduced merely as a means of relieving dehydration, it occurred to us that it might at times be a useful method of feeding in weakly or dull babies such as those who are immature or jaundiced. It might have been thought that vomiting would make the technique impossible; but, on the contrary, we have found it a means of stopping even most persistent vomiting. It is very rare for a baby to vomit at all while the gastric drip is running, and we have never had to stop one for this reason. Another possible danger was the production of an oesophagitis, but in the very few cases as yet seen at necropsy this has not been found.

The following cases illustrate the uses of the method.

1. Infant S. Twelve days old on admission to sick nursery, 1 lb. 2 oz. below birth weight. Severe vomiting and diarrhoea. Baby looking moribund. Gastric drip started. Sulphamezathine tab. 1/4 q.q.h. and pulv. kaolin ʒii q.q.h. Drip continued for three days, during which time the fluid was gradually changed from saline to "secway" and then to human milk. When weighed on the fourth day it had gained 7 oz. Vomiting had stopped, the motions were normal, and it made a steady recovery.
2. Infant B. Ten days old. Admitted to sick nursery with diarrhoea and vomiting, 1 lb. below birth weight. Sulphamezathine tab. 1/4 q.q.h. and pulv. kaolin ʒii q.q.h. On account of dehydration put on gastric drip of "secway" for 24 hours. Gradually increased to 2-in-1 cow's milk–water mixture. Nine days later discharged 1 oz. over birth weight.
3. Infant J. Four days old on admission to sick nursery. Very persistent vomiting, even of saline. Marked dehydration. Found to have very inflamed ear-drums. Sulphathiazole tab. 1/4 q.q.h. given. Gastric drip of saline started. No further vomiting. Dehydration relieved. Ears cleared up. Made steady recovery.
4. Infant R. Birth weight 3 lb. Extremely weakly. Fed for one week with gastric drip, during which time it lost only 2 oz. It was then strong enough to be fed from a bottle. It is now 7 weeks old and weighs 4 lb. 12 oz

In conclusion we would say that for safety, simplicity, and effectiveness in the relief of dehydration we find the gastric drip excellent, and think that its more frequent use in neonatal and infant nurseries would save lives, time, and anxiety.

Urinary Retention in an Infant caused by Malignant Growth

Acute retention is not a common complaint in infants. The following case occurring in a baby girl of 6 months may therefore be of interest.

CASE HISTORY

The infant was well developed and had had no ailments until a week before her admission to hospital. The doctor had been called in because the child was in obvious pain and had not passed urine that day. The bladder was distended, and about a pint of urine was withdrawn through a catheter. Catheterization had to be repeated daily for a week.

On admission to hospital a fine rubber catheter was passed quite easily and tied in to drain the over-distended bladder and allow it to recover its muscular tone. After seven days' continual drainage the catheter was removed and for three days normal micturition occurred. It was noticed during this time that the baby was constipated and often became distended with wind. Retention of urine became acute again on the fourth day after removal of the catheter, and so a general anaesthetic was given to allow of a complete examination and to insert a suprapubic self-retaining catheter.

Rectal examination revealed a large, smooth, rounded swelling arising from behind the rectum, lying in the hollow of the sacrum and almost completely filling the pelvic cavity. It was solid, moderately hard in consistence, and about the size of a Jaffa orange. It was hardly possible to insinuate the finger between the tumour and the symphysis pubis. An unsuccessful attempt to aspirate its contents confirmed the solid nature of the tumour. From the abdominal aspect nothing was visible or palpable.

A week later, although urine was draining freely through the suprapubic catheter, it was apparent that intestinal obstruction was becoming more severe. Laparotomy was decided upon with a view to determining the nature of the tumour, seeing if it could be removed, and if not, then relieving the obstruction by colostomy. Through the abdominal incision it was found that the tumour filled the true pelvis almost completely. The rectum and pelvic colon were pushed forwards and to the left, and the latter was compressed at the level of the pelvic brim. The posterior parietal peritoneum (which was intact) was incised to the right of the pelvic colon and by blunt dissection the tumour was separated posteriorly down as far as the middle of the sacrum without much difficulty. Lower down it was firmly adherent to the bone, and it became obvious that it could not be removed. A small section was taken for biopsy. Little or no haemorrhage was encountered. Sudden collapse necessitated the rapid termination of the operation, and the baby died before it could be returned to the ward.

The pathological report, for which I am indebted to Prof. M. J. Stewart and Dr. R. M. Heggie, was as follows: "This is a highly malignant and embryonic teratoid growth arising from the intermediate cell mass. It is essentially adenocarcinomatous in nature and papillary in type. The exact origin cannot be stated."

Skipton. PHILIP H. MERLIN, F.R.C.S.Ed.

Reviews

AMERICAN MEDICINE

Textbook of Medicine. Edited by Russell L. Cecil. Sixth edition, revised and entirely reset. (Pp. 1,566; illustrated. 55s.) Philadelphia and London: W. B. Saunders Company. 1944.

This well-known American textbook now reaches its sixth edition, for which it has been revised and entirely reset. It has much the same arrangement as any other general textbook. It is printed in a type that is easily read, and throughout its pages are a judicious selection of illustrations. Many of the articles are accompanied by short lists of references to the literature. The writers of the various articles must find it difficult to know what to select from the vast literature that has grown round so many of the subjects dealt with, and there must be a natural tendency on the part of the contributor to favour references to his own work. As the writers are chosen for special knowledge of their subject this is inevitable, but we cannot help feeling a doubt about the usefulness of short reference lists: within the space allotted to them much that is important must obviously be omitted.

An attractive feature of this textbook is the inclusion here and there of short historical notes in small type—for example, the interesting historical note on scurvy, in which we are glad to see references made to Sir Thomas Barlow's description of infantile scurvy; but we find in the bibliography James Lind's *A Treatise of the Scurvy,* but not Sir Thomas Barlow's article in the *Medico-Chirurgical Transactions, London* (1883, **66,** 159). The complete omission of the names of Ronald Ross and Patrick Manson from the historical note on malaria comes as a surprise to the English reader, who will perhaps find this book of most value to him as an index to therapeutic methods in current American medicine. It is, for example, interesting to read in the section on the treatment of pneumonia that the use of sulphapyridine has been almost completely discontinued because of its toxic effects, and that the drug recommended in the U.S.A. is sulphadiazine. And of alcohol in the treatment of this disease it is observed: "The consensus seems to be that it should be administered only to patients who are chronic alcoholic addicts." The article on pneumococcal pneumonia is written by the editor, Dr. Russell L. Cecil, whose contribution to the discussion on serum treatment of pneumonia before the Section of Pharmacology and Therapeutics at the Centenary Meeting of the B.M.A. in London in 1932 will be remembered by those who attended: it was subsequently published in the *Journal* (1932, **2,** 657). On the efficacy of serum in the treatment of pneumonia he observes that it now seems to be of value in the treatment of patients who cannot tolerate sulphonamides, or who do not respond satisfactorily to sulphonamide therapy within 24 to 48 hours.

This textbook is well up to date, and includes, for example, references to penicillin, an article on virus pneumonia, and new introductory chapters on such subjects as the rickettsial diseases, diseases of metabolism, and diseases of the ductless glands. A useful feature is the 3½ pages at the end of the book giving a list of "normal values for clinical examination." Dr. Cecil's textbook is a great credit to American medicine.

VENEREAL DISEASES

The Venereal Diseases. A Manual for Practitioners and Students. By James Marshall, M.B., B.S. (Pp. 384; illustrated. 21s.) London: Macmillan and Co. 1944.

For some years now, and particularly during the war, venereal diseases have assumed ever greater importance, which is likely to increase after the war is over. With the advent of the sulphonamides and penicillin it seems likely that more and more cases will be treated by the general practitioner in the future. Hitherto the medical student has received little instruction in venereal diseases, and consequently the average general practitioner knows little about them. Up to a few months ago there was hardly a single textbook on the subject published in this country which was up to date; therefore the appearance of *The Venereal Diseases* by James Marshall, following closely on *Handbook on Diagnosis and Treatment of Venereal Diseases* by A. E. W. McLachlan (reviewed in this column on Aug. 12), gives the student and practitioner the choice of two excellent textbooks, to which they may refer for anything in connexion with V.D. which is not exclusively the province of the expert. Major Marshall needs no introduction—he is well known to many Londoners as ex-senior R.M.O. at the London Lock Hospital, and to Service medical officers as command specialist, Eastern Command.

The book is divided into four parts, dealing respectively with gonorrhoea, syphilis, other venereal and allied diseases, and technique; in addition there are appendices on sociology of V.D. and on special equipment, together with a short bibliography. The section on gonorrhoea is particularly good, and sound views are expressed on the use and interpretation of the complement-fixation test. The sulphonamides are handled skilfully, though it might have been well to stress the importance of fluid output rather than intake in the avoidance of haematuria; an intake which is sufficient in temperate zones will not be enough in the Tropics. The section on syphilis is necessarily curtailed by limitations of space, but is adequate; there are numerous excellent illustrations, and most of the coloured plates are beautifully produced, though a few are somewhat lacking in definition—e.g., Plate V. The treatment of early syphilis is the continuous type and is certainly thorough—the dosage is perhaps rather heavier than that commonly employed in this country. "Other Venereal Diseases" are rather crowded out: a fuller section on non-gonococcal urethritis would have been welcome, because not only is this condition becoming much more common, but it is often very difficult to cure. The practical instructions on technique are most valuable and will be very helpful to the general practitioner.

This is a book which can be recommended warmly; if the literary standards are hardly those of Mr. Winston Churchill, the meaning is clear, and the facts are set out with commendable accuracy.

HUMAN CONFLICTS

Foundations of Human Conflicts. A Study in Group Psychology. By William A. Brend, M.D., M.R.C.P. (Pp. 212. 15s.) London: Chapman and Hall. 1944.

The late Dr. William Brend as his last literary task produced a book of great interest not only to his own two professions of medicine and law but also to all those who are concerned directly or indirectly with the future planning of society.

If individual man is improving in intellectual capacity it would appear that in the mass he is not guided by reason but is swayed by childish emotions. Yet it ought to be possible to educate society, for instinct properly defined does not seem to exert much influence on the behaviour of the nations. The individual is strongly moved by directly experienced emotion; but the behaviour of the crowd is determined by propaganda, which uses indirect derived emotion, and this is much less honest. Certainly man tends to form himself into groups, but he does not do so as a result of the action of uncomplicated herd instinct. The group is formed and maintained as the result of emotion, not reason. This may be the direct love of a leader or cause, or the indirect hate of an imaginary or propaganda-clothed enemy. Unfortunately direct love, which should result in universal brotherhood, is less potent than indirect hatred, because in private life expressions of hatred tend to be suppressed by society, and so more readily come out in the mass. The chief modern groups are nations, but neither nationality nor race has any real logical existence, and a nation is only the population or area controlled by a ruler. Patriotism is not innate and is only a derived emotion established by education. Unlike science and knowledge, which have a universal appeal, patriotism is sectional and is the real enemy to peace. War is not due to an instinct of pugnacity or to mass sadism or to the evolutionary process or to divine displeasure; these explanations are mere rationalizations; even religious conflict is not primitive. It is increased by the identification of religion with patriotism, and so a State Church is often an evil influence, for it is associated with the ruling caste and so tends to promote class conflict, which, although softened and modified by tradition, is very intense even in Britain. There is also conflict between the young and the old, and, in the author's opinion, juvenile delinquency is most often due to frustration and rebellion against restrictions imposed by the old. So, too, in the matter of sex, there are too many restrictions; the author thinks that the age of consent is too high, and at 17 both sexes should be free to marry on their own volition without having to obtain the consent of their parents. He thinks, further, that the natural healthy curiosity of children and desire to use the mind are stifled by modern education, which is concerned to instil religious emotion to promote the development of emotional loyalty and to ensure the perpetuation of established social institutions. The author's solution is the establishment of children's colonies for all over 9 or even younger, where there will be a minimum of discipline and compulsion. As to the fall of the birth rate, this is primarily due not to economic causes so much as to the postponement of marriage. Monetary grants are not the answer, but the promotion of earlier marriage and reform of the marriage and divorce laws. He would even favour the institution of temporary contracts, with State provision for children born of such contracts which did not become permanent. Finally, government should be founded on reason based on knowledge, and it must cease to further emotional and ideational conflicts for their own sakes.

Obviously many of the author's suggestions are provocative, but they are logically and lucidly presented, and even his opponents will gain much by reading his book, since if they are to refute his arguments they will have to put their own ideas into order.

Notes on Books

The second edition of Mr. EUGENE WOLFF'S *A Pathology of the Eye* (H. K. Lewis and Co.; £2 2s.) follows closely the arrangement of the first edition, reviewed in these columns on Jan. 19, 1935. The illustrations have grown from 124 to 212, without any substantial additions to the text. Room has been made for additional material by the deletion of some of the older matter, and the present volume is more consistently a textbook on the morbid histology of the eye than the original edition.

The last three editions of *Murrell's What to do in Cases of Poisoning* were prepared by Dr. P. Hamill, and the author of the new (fifteenth) edition is Dr. HAROLD G. BROADBRIDGE, coroner for the county of Middlesex Western District. The book can therefore be recommended to doctors as informing them what steps a coroner expects them to take when they are called to see a person who is poisoned. Further, they can prime themselves before attending an inquest with information which no coroner will be likely to question. The publishers are still H. K. Lewis and Co., and the price is 8s.

Preparations and Appliances

ILLUMINATED ELECTRODE FOR RETINAL DETACHMENT OPERATION

Mr. T. COLLYER SUMMERS, F.R.C.S., writes:

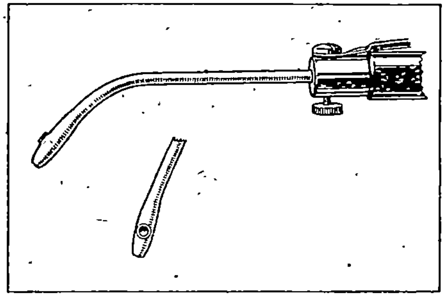
In introducing this method of dealing with retinal detachments that have posterior holes, I feel that it would be helpful if the steps which led up to the development of this operation were recounted.

In 1934, after having done detachments for some time, and having experienced late degeneration of the macula in some cases although the macula had never been detached, I came across the case reported at the Royal Society of Medicine by myself in which, before operation, only a 40-degree segment of the field was present, and this segment after operation was found to be very greatly diminished in sensitivity. This led me to think that macular degenerations and other field defects not explained after successful operations were due to the electric current used, and that more accurate location should be attempted than had been used up to that date. Various methods were tried to locate the hole more accurately, and the best of these was that introduced by Prof. Weve of Utrecht, in which the site of the hole on the sclera was shown by indirect ophthalmoscopy, the assistant then inking the spot so that the flat plate could be applied.

I then conceived the idea of finding the hole by transillumination, and designed a transilluminator, which, with the assistance and kindly co-operation of Messrs. Theodore Hamblin, was shown at the Ophthalmological Congress with other instruments. At that meeting I pointed out that the transilluminator had on one occasion shown the hole up perfectly, but that on subsequent occasions I had never been able to get it to work satisfactorily. It was considered at the time that, if it had worked once, the instrument could probably be so adapted that it would work in the future. The disadvantages of the transilluminator then in use were that it was too cumbersome and the light was too diffused.

A few months later Mr. Gray Clegg of Manchester designed an ideal transilluminator for the purpose, but for some months I was unable to obtain any successes with this instrument. The transilluminator which was being used was a perfectly naked light, and diffusion was so great that no details of the fundus could be accurately focused, let alone the edges of a hole. I accordingly suggested to Mr. Brown, of Messrs. C. Davis Keeler, who was using this apparatus with me, that ground glass be introduced into the Gray Clegg illuminator, and the result was an unqualified success. Holes at the macula showed up clear and sharp, quite as well by transillumination as by reflected light, and in one instance better. Having discovered that the hole could be seen, it was then decided to put an electrode round the light. This was done and the new instrument as seen in the accompanying sketch was devised and made by Messrs. C. Davis Keeler. In three cases this instrument has been used with success. The technique so far has been as follows for macular holes:

An incision through the conjunctiva and Tenon's capsule has been made on the outer side of the globe, the external rectus divided, and catgut stitches put in the muscle, ready for suturing to the scleral stump at the end of the operation. A perfect view of the field of operation is thus obtained. The electrode transilluminator is then introduced in the same way that any other electrode would be, with the difference, of course, that the light is on. The theatre being dark, an old-fashioned Morton non-illuminated ophthalmoscope with the mirrors removed is then used to look through the pupil. When the light is seen to be opposite the hole, which is easily recognized, the edges of the tear being almost "lit up," the technician working the apparatus then switches on the current at 120 milliamperes for 5 seconds. So far I have not observed any definite swelling of the choroid. All that has happened is that the hole has become less distinct as the current has flowed. In the cases done so far two applications have been made so as to be sure that the hole was properly covered, whether necessary or not. Fluid was let out by the 2-mm.-thick diathermy needle and suction. The cases made satisfactory recoveries, with, of course, no standard of central vision.



The technique of using this instrument has not by any means been perfected. It is definitely not easy to handle in holes not far back from the ora serrata, as I have found it impossible to keep the light in position with one hand and hold the ophthalmoscope in a suitable position with the other. One great difficulty that has been experienced, and is still being experienced, is that the patch of illuminated retina is so small that it is very difficult to find. It is important, before applying the transilluminator, to make quite certain that the sclera is dry and free from blood. This has been achieved up to now by packing off the area with stryphnon swabs.

This method is introduced as one which, when perfected, might be much better and more accurate than those used at present.

"SYNAPOIDIN"

Messrs. Parke, Davis and Co. have recently prepared for sale "synapoidin," which is a gonadotrophic preparation containing both chorionic gonadotrophin and the gonadotrophic hormone obtained from the anterior lobe of the pituitary. In animals it exerts both follicle-stimulating and luteinizing effects, and it is standardized in terms of the amount required to increase the weight of the ovaries of immature rats five-fold. It is used for the treatment of sterility when there is no physical reason, and also for the treatment of amenorrhoea, even of long duration. It seems doubtful whether the simultaneous administration of both the follicle-stimulating and the luteinizing hormones can achieve the best result in sterility. A more rational method would seem to be to inject the follicle-stimulating hormone (obtained from pregnant mare's serum) from the 5th to the 15th day of the cycle, and then to give chorionic gonadotrophin for the next 10 days when the luteinizing effect is wanted. This has been done with promising results in America by E. C. Hamblen and others. It will be interesting to discover whether the use of "synapoidin" is equally successful. It is a potent preparation to be used with care.

LOCAL GOVERNMENT BOUNDARIES

It is a very cautious exercise in reconstruction which is presented in the new White Paper on Local Government in England and Wales.[1] If any time can be more suitable than another for recasting local authority structure it is surely at the end of a war during which a great deal that was traditional and established has already been superseded. A time also when tasks are being thrust upon local government—the replanning of bombed cities; housing, in many areas on an immense scale; educational provisions under the recent Act, and the projected National Health Service—seems to offer occasion for a survey of existing machinery, scrapping the obsolete and installing new. But the White Paper, which is the result of discussions between the Ministry of Health and the Associations of Local Authorities, contains only one recommendation—the setting up of a Boundary Commission. This will do little more—though it will certainly do it with a national perspective—than county councils in association with the Ministry can do at present in readjustment of areas.

Those who expected to see radical changes which would make the administrative map of England unrecognizable, with perhaps a dozen regions, analogous to the Civil Defence regions, in place of half a hundred counties, and the creation of large single cities to cover such "conurbations" as the Tyneside towns, will be disappointed. Even the urgent problem of London, where the county contains less than half the population of what may be called the metropolitan region, is immured from present change, although an inquiry is promised. Neither London nor Middlesex, which is a county entirely urban, without any rural districts, is to come within the ambit of the Commission.

The Government is opposed to the centralization of services hitherto accepted as local. It is opposed also to regional administration, against which, apparently, the local government associations expressed themselves unanimously. It is held that whatever changes are necessary can for the present be carried out within the framework of the existing county and county borough system. What George Borrow called the "genuine spirit of localism" is to be preserved. The existing pattern of local government is held to have justified itself, especially in the supreme test of war, though whether this result is due to the energy and enlightenment of the administrators or to the excellence of the fabric is an open question. Local government has always enlisted a vast amount of public-spirited service, often stimulated by the political feeling so marked in many towns. It has proved an excellent school for administrators, many of whom—outstanding names in this and the last generation will come to mind—have graduated from local councils to the highest places in national government. The White Paper assures us that there is no ground for any fear that the work of democratic local government will diminish. On the contrary, it seems as if the State must delegate more of its multiplying responsibilities to local bodies.

Local government areas can never be arranged quite like the squares of a chessboard, but there could be very much better concentration of authorities and readjustment and simplification of areas, with the joining up of poor areas to neighbouring richer ones so that inequalities in the standard of provision might so far as possible be redressed. It is true that there is not now the chaos to which Mr. Goschen called attention sixty years ago: a chaos of jurisdictions, rates, franchises, and areas, with 27,000 independent local authorities taxing the ratepayers by eighteen different kinds of rates. But since 1888, and even since 1929, social change and the growth of industry and locomotion have made many boundaries irrelevant. Large cities, if their municipal transport was restricted to their boundaries, would be unable to serve their own housing estates. On Tyneside the houses are continuous throughout the areas of sixteen local authorities, which authorities, incidentally, have, or had before the war, eleven separate hospitals for infectious diseases.

Under the present system county boroughs are responsible for all local government services in their areas; in the administrative counties the responsibility is shared between county councils and councils of non-county boroughs and of urban and rural districts. But county boroughs range in size from Birmingham with its million population to Canterbury with its 25,000, and the population of administrative counties varies within similar extremes. Conditions, moreover, are constantly changing, with growth and transfer of population and industry. A river or range of hills which was a natural boundary, and still is an administrative one, may become not so much a partition between communities as a spine holding them together. Numerous small boroughs with ancient charters have limits as closely fixed as a walled town of the Middle Ages, but modern transport has made large surrounding rural districts in many respects a part of the town and the town a part of the country.

The need for overriding the frontiers in order to bring most economically certain services to the community is recognized in the idea of joint authorities for planning or executive purposes. The objections to joint boards are, first, that they are not directly elected bodies, and, secondly, that the multiplication of *ad hoc* authorities is undesirable. The White Paper states that the Government does not underrate these objections, but it still holds that, as against centralization or regionalization, the method of joint authorities is to be preferred as a means of obtaining combined action where a co-ordination of services between two or more areas, whether counties or county boroughs, is necessary. The White Paper on a National Health Service proposed that, particularly for hospitals, larger areas of local administration than at present exist should be placed under the control of joint boards. It stated (Appendix C) "that the need to settle areas of proper size and resources for certain aspects of the service is urgent and that (temporarily at least) the joint-board seems to be the only practicable means of doing this." In his recent statement to the Representative Body of the B.M.A. the Chairman of Council said that since the issue of the White Paper the joint board had rather faded from the picture. But it fills the frame in this new White Paper, and although the "specific purposes" are "housing, water-supply, and so forth," hospitals are implied, because earlier in the Paper it is mentioned as an argument of those who want to recast the whole local government system that hospital services need to be planned, and in some cases administered, over a wider area than a county or county borough.

---

[1] Cmd. 6579, H.M. Stationery Office. (4d. net.)

As already stated, the only recommendation is the establishment of a Boundary Commission, an itinerant and executive body, whose task it will be, by holding local inquiries, to ensure that local government units are of such size and shape and have such financial resources as to provide a satisfactory administration. It will have power to create and extend county boroughs and to reduce the status of small county boroughs and counties by uniting them with contiguous ones. It will also bring to the notice of the Minister any case in which a combination of authorities for particular purposes is desirable.

The special problem of London is left over for the time being, pending inquiry by an authoritative body. Middlesex also is left in the air. If the Commission began to create county boroughs in Middlesex it might cover the whole county with them, and destroy county government. How closely bound are the counties of London and Middlesex is instanced by the Hammersmith Hospital, to which the British Postgraduate Medical School is attached. It is administered by the L.C.C., but is at the western extremity of the county, and Middlesex is its "catchment area." The reason given why the present time is thought not opportune for extending the boundaries of the County of London is that the tasks upon which local authorities in and around London are and will be engaged in recasting their services should not be interrupted by throwing the whole problem into the melting-pot. It is extraordinary what different conclusions different minds will draw from the same premisses. Many would argue that the very fact that these tasks—the new health service, for example—are imminent calls for a reconstruction of the system in advance. There should be new wineskins for the new vintage; otherwise the skins may burst and the wine be spilt.

CHEMOPROPHYLAXIS OF RESPIRATORY INFECTIONS

The value of small doses of sulphonamide drugs in controlling the spread of infection by a sulphonamide-sensitive organism has been tested in more than one direction lately. Sulphonamide therapy is particularly effective against the meningococcus, and during the epidemic of cerebrospinal meningitis in 1940–1 it not only cured the clinical infection but also eliminated the meningococcus from the nasopharynx of affected patients and of contact carriers. It was therefore a logical step to use it for preventing the spread of infection in Army training units where the occurrence of clinical cases of cerebrospinal meningitis together with a high meningococcus carrier rate indicated the likelihood of further trouble. This has been done in more than one American camp, and the remarkable fact has been established[1] that a dose of 1 g. of sulphadiazine twice daily for two days will bring an outbreak of cerebrospinal meningitis to an abrupt end. Outbreaks of streptococcal tonsillitis and pharyngitis, with sometimes a high incidence of acute rheumatic fever in their wake, have been prevalent among both Navy and Army recruits in training units in the U.S.A., and the successful prophylactic use of sulphonamides in preventing rheumatic relapses through the winter months encouraged American workers to try the same methods for controlling respiratory, in particular streptococcal, infection in these training camps. Two recent reports show what measure of success has been attained. Holbrook[2] tested the effect of sulphadiazine in doses of 1 to 2 g. daily for short (2 to 3 days) and longer periods (up to 3 months) on the hospital admissions for respiratory infections among American Air Force personnel. He reported reductions in incidence of 50% to 75%. It was stated that about 50% of the admissions ordinarily showed clinical and laboratory evidence of streptococcal infections. Reactions due to the sulphonamide were rare. In a specially studied group of 40,000 men, only 13 (0.03%) lost time off duty, mostly with skin rashes developing within 1 to 16 days of starting the drug; two patients who developed febrile reactions gave a history of previous sulphonamide-sensitivity; one case of haemolytic anaemia responded promptly to blood transfusion. Coburn,[3] who indicts the streptococcus for the heavy toll it has taken in American naval establishments, also claimed that sulphadiazine in 1-g. daily doses could dramatically reduce the incidence of respiratory infections. For example, in one unit where "catarrhal fever," tonsillitis, scarlet fever, and acute rheumatism were all rife a sharp drop in the monthly incidence of respiratory infections from 150–200 to 20 per 1,000 men followed the introduction of sulphonamide prophylaxis in February. In another camp alternate companies were given 0.5 g. sulphadiazine daily from November on, and the subsequent incidence of cases requiring hospital treatment for respiratory infection was three times greater in the control than in the treated group. Proven clinical streptococcal infection in the control group was 24 times greater, and probable streptococcal infection (positive throat culture) 11 times greater, than in the treated group. Coburn believes that short sulphonamide courses lasting a few days are inadequate to prevent further recrudescence by checking the spread of streptococcal infection.

The possible dangers from sulphonamide prophylaxis are the induction of sulphonamide-sensitivity in the patient, the occurrence of disabling and even fatal sulphonamide reactions (toxic or allergic), and the development of drug-fastness in respiratory pathogens. With regard to the first of these risks, Holbrook and Coburn found that men put on repeat prophylactic courses showed no greater incidence of sulphonamide reactions than other groups. Coburn reported an incidence of drug reactions between 0.2% and

[3] Ibid., p. 88.

0.7% in all "treated" groups, mostly mild skin rashes during the second and third weeks of prophylaxis. Severe reactions—exfoliative dermatitis and granulocytopenia—occurred in 0.01% of cases. The one death in his series was ascribed to leukaemia. The production of drug-resistant strains of the haemolytic streptococcus and the pneumococcus would theoretically appear to be the greater danger. However, without producing bacteriological evidence, Coburn contends that this did not happen among his "treated" groups because (1) there was no increase of any one serological type of streptococcus during prophylaxis; (2) the streptococcus did not supplant other bacteria in the throat flora; (3) streptococcus morbidity was uniformly reduced in incidence; and (4) "treated" patients who afterwards developed streptococcal infection responded well to sulphonamide therapy. But it would be unwise to be too sanguine about this possible danger. Sulphonamide-resistant streptococci have already been observed to spread in wards where open wounds[4] and measles patients[5] were being treated with the drug, and more careful investigation of this hazard is needed.

At the moment it seems reasonable to recommend sulphonamide prophylaxis for the control of outbreaks of meningococcal and streptococcal infection, and for the prevention of rheumatic relapses. For the first of these the effective dosage of 2 g. daily for 2 to 3 days is practically without risk for the community unless there are persons in it already sensitized to the drug; for the second, a dosage of 1 g. daily would have to be continued for perhaps 3 to 4 weeks, when sensitivity is likely to show itself; for rheumatic fever prophylaxis must be continued throughout the winter. Sulphanilamide in doses of 1 to 2 g. daily has been the drug of choice, and the latest American report[6] (which also summarizes earlier work) is encouraging as regards both prophylaxis and the minimal occurrence of toxic drug reactions. Thus among 88 rheumatic patients "treated" for 181 patient-seasons there were only 5 streptococcal infections (2.7%) and 2 rheumatic relapses (1.1%), whereas in the control group of 107 patients observed for 138 patient-seasons there were 54 streptococcal infections (39%), and 19 definite plus 7 mild or possible rheumatic relapses (19%), with 3 deaths. Sulphonamide prophylaxis for the rheumatic patient may be risky, but it is justifiable.

TREATMENT OF "WOUND SHOCK"

The Medical Research Council has just published a revision of its practical memorandum[7] on the management of wound shock. The document gives an impersonal digest of practical views reached as a result of five years' observation and research. It is now realized that shock is a complex state resulting from a multiplicity of causes, but most often from haemorrhage. For this reason the word "shock" is enclosed in inverted commas throughout the document. The sequence of events in haemorrhage is carefully described, and thereafter other causal factors, such as burns; crushing injuries, infections, and fat embolism, are outlined. On the basis of this logical presentation the treatment is described. All along the line practical advances call for comment. The frequency and importance of vasovagal collapse after blood loss are stressed: this condition is characterized by a slow pulse and a fall of blood pressure due to dilatation of muscle arterioles, as shown by the workers at the British Postgraduate Medical School.[8] New views on burn shock and on crushing injuries emanate from the M.R.C.'s units in Glasgow and Newcastle. The factor of tissue trauma studied by the Sheffield group[9] is mentioned, and the importance of early removal of injured tissue is emphasized. All these parts of a wide field of research endeavour have been welded together into a practical and simple exposition by a committee including senior leaders of proven wisdom as well as such field observers as Prof. W. C. Wilson and Dr. R. T. Grant. Transfusion remains the key to treatment in the majority of cases, and the importance of transfusing until the blood pressure is normal is stressed. The place of serum and plasma infusions is carefully defined, and useful practical details are given, especially for their employment in burns. There is now less insistence on oxygen administration, and overheating is considered dangerous. An alkaline diuresis may prevent but not cure the anuria which results from crushing injuries. (A misprint here of ounces for drachms.) The great number of possible blood substitutes from isinglass to bovine albumin are wisely omitted from discussion. For use in civilian work a few words might have been added on the harmful vasodilatory influence of alcohol in cases of street accident.

There still remains much work to be done on the reactions of the body to injury. The changing outlook may well be outlined by dissecting Harkins's[10] pithy definition of shock as "progressive vasoconstrictive, oligaemic anoxia." While acute oligaemia certainly produces a common form of "shock," the Postgraduate School workers[11] have demonstrated that low blood volumes often occur in severe anaemia with a high cardiac output. Oligaemia as such can therefore be compensated by a series of reactions as yet unstudied by laboratory physiologists. Vasoconstriction was thought to be a constant feature of "oligaemic shock." But the occurrence of "vasovagal" vasodilatation after haemorrhage now makes the general accuracy of this concept doubtful. The multiple factors at work in an injured man may produce vasodilator reactions more often than has been imagined. Tissue anoxia from poor blood flow, accepted as part of the shock story a few years ago, now seems to be ill understood. Frank and Fine[12] have shown that oxygen administration, even at a pressure high enough to compensate for sluggish blood flow, will not bring about recovery in "shocked" dogs. Are parts of the circulation completely shut down, as Rous and Gilding[13] observed, so that the extra oxygen supply does not get to the parts where it is needed?

It is to be hoped that these problems will be closely pursued, for their solution may reveal new physiological mechanisms of fundamental importance. Much work on oxygen lack and cardiovascular reactions to it has been done in the Air Force under a cloak of secrecy. Is it necessary to keep this information so closely guarded any longer? Perhaps some of it may provide much-needed clues for those struggling with the problem of death from trauma in which no vital organ has been directly involved.

HERPES ZOSTER

Recent interest in herpes zoster has been focused upon aetiological and bacteriological aspects, and it is now commonly accepted that the condition is due to a filterable virus related to, if not identical with, that of varicella. It is also generally believed that the virus causes inflammatory changes in isolated spinal or cranial sensory ganglia, the posterior grey matter of the spinal cord and adjacent leptomeninges, and that these lesions account for the well-known clinical manifestations of a vesicular cutaneous eruption, radicular neuralgia, segmental palsies, and sensory disturbances. The main pathological features of herpes zoster were discovered in 1861 by von Bärensprung, who gave such a plausible account of the condition that later generations tacitly assumed that his anatomico-pathological observations provided a satisfactory basis for the clinical syndrome. It is for this reason that a recent paper by Denny-Brown, Adams, and Fitzgerald[1] deserves general attention, as the authors set out to expose the inadequate evidence for views widely accepted and sanctioned by tradition. On the strength of their investigations they are led to assume that the clinical phenomena of herpes zoster require more than a ganglionic lesion for their explanation, and depend, *in part at least*, on a poliomyelitis involving the anterior horn cells and an independent motor neuritis. Likewise, the combination of a herpetic eruption in the external auditory meatus and palsy of the facial nerve, known as the "Ramsay Hunt syndrome" or "geniculate herpes," cannot be explained by the affection of a cranial ganglion alone, but presupposes an independent motor neuritis of the facial nerve. It is historically interesting to note that the geniculate ganglion from which the name of the syndrome is derived was not found involved in the case of Denny-Brown and his associates. There is, however, some suggestion, though not yet any definite evidence, that in the Ramsay Hunt syndrome the ganglia of the vagal and glossopharyngeal nerves may be affected.

TENSION IN TUBERCULOUS CAVITIES

The treatment of large, thin-walled, spherical tuberculous cavities in the lung, commonly called "tension" cavities, has aroused much discussion, because these lesions often fail to respond to the usual collapse measures. The pioneer work of Coryllos helped to explain the mechanism by which such cavities are formed, and Monaldi gave us a new method of attacking them when he described his technique of suction drainage. A recent contribution by Vineberg and Kunstler[2] to the rapidly growing literature on this subject voices a plea for careful differentiation between true tension cavities and others which, though radiographically similar, do not have a positive pressure within them. These authors state that drainage is often applied to any large cavity without differentiation, though in this country the work of Price Thomas,[3] Sellors,[4] and Maxwell and Kohnstamm[5] has pointed the way clearly to the correct use of this treatment.

After a useful survey of the literature Vineberg and Kunstler give a clear account, supplemented by useful diagrams, of the mechanism by which tension cavities are produced. In the bronchus draining such a cavity a valvular obstruction allows air to enter but not to escape from it; the usual collapse measures, such as pneumothorax or thoracoplasty, will therefore often fail to close a tension cavity—it continues to be inflated in spite of adequate collapse of the surrounding lung. But, as Price Thomas has pointed out, the collapse will sometimes alter the mechanics of the draining bronchus in such a way that it becomes completely obstructed, and the cavity then closes. Vineberg and Kunstler believe that all tuberculous cavities with a diameter greater than 2.5 cm. should be needled before any other treatment is undertaken. If the pressures in the cavity are persistently positive it should be treated in the first instance by closed drainage with the Monaldi technique, followed by continuous suction. These authors state that giant cavities, which might be called tension cavities simply from their *x*-ray appearance, are really of two types—*true tension cavities*, and others in which the intracavitary pressures are normal, showing that there is no valvular bronchial obstruction. The latter respond well to the usual collapse measures, whereas the tension cavities do not; hence the importance of ascertaining the pressures within the cavity before starting treatment.

Continuous suction drainage will often reduce the size of a tension cavity until it is no more than a tube-track, but Vineberg and Kunstler agree with Sellors that permanent closure can rarely be obtained by drainage alone. When the suction has done its work it must be followed by thoracoplasty to ensure complete healing, but a very limited thoracoplasty is often enough to achieve the desired result. In the case of certain giant tension cavities closely adherent to the chest wall, Vineberg and Kunstler state that an anterior-stage thoracoplasty before drainage will give sufficient relaxation to allow the cavity to contract; this is followed by a posterior-stage thoracoplasty when drainage has reduced the cavity to a minimum. These authors also report that, for the purpose of taking pressure readings, they have needled 150 cavities without any complication. The depth of the cavity was determined by tomography in each case, and they took great care always to obliterate the pleural cavity at the site of the puncture, and to avoid air embolism. In a small series of 25 tuberculous tension cavities treated by suction drainage, supplemented by thoracoplasty, rather more than half were closed successfully.

"A HOUSE OF BOOKS"

In 1931 Messrs. H. K. Lewis and Co., Ltd., medical librarians, publishers, and booksellers, opened their rebuilt and enlarged premises adjoining University College, London, at the corner of Gower Street and Gower Place. The year 1945 sees the completion of the centenary of that firm, so well known to the medical profession. Henry King Lewis started business in 1844 at what was then 15, Gower Street North, afterwards to be known as 136, Gower Street; the actual date cannot now be traced, but it was towards the end of the year. Mr. H. L. Jackson, nephew of the founder of the firm, whose own association with it dates back for 56 years, has for some time been preparing a short account of H. K. Lewis and his work as a publisher and bookseller, and of the later growth of the business. This book, when published, will fittingly mark the hundredth anniversary, though formal celebration of the event must wait until after the war. Mr. Jackson succeeded Mr. E. J. Sowerby as chairman of the company 20 years ago, and many readers will be glad to know that notwithstanding wartime difficulties and anxieties he continues as governing director. No one now living can tell when the cordial relations began between "Lewis's" and the B.M.A. and its *Journal*, but it is a very old comradeship in the service of medicine.

SIGHT-SAVING CLASSES

BY

N. BISHOP HARMAN, M.B., F.R.C.S.

In a leading article in the *Journal* of Oct. 21, 1944, entitled "Partially Sighted Children" there is an excellent account of Mrs. Winifred Hathaway's well-written book on the experiences of American educationists of sight-saving classes. Her figures show that there are 630 of these special classes in 31 States. This indicates how keen has been the development of this special provision for children with defective sight; but the fact that there are still some 50,000 children who are held to require it leads to a question addressed to me—namely, What are the technical requirements and potentialities of the school for the partially sighted?

All work of these sight-saving classes has been of interest to me, and I think I can do well for them by showing how they came into being. Early in this century there was no provision for the care of the eyesight of children in the increasing number of elementary schools established under the Act of Parliament of 1871. There were fine new school buildings in London; they were full of children. The teaching was good. But no one thought of the eyes of the children until Dr. James Kerr became medical officer of the Education Department of the L.C.C. When I heard it was proposed to appoint some of us young eye men to go to the schools and test the eyesight of the children I went to see him, and he allowed me to join in the work. I felt that this experience among the children of our great city would have an interesting reflection upon hospital work; I should then see the healthy as well as the sick. I was given a fine area of schools, of which Hackney was the centre. About half a dozen started this work all over London, and we spent three half-days a week at the schools. I found it of great interest in that it showed me the variations in eye health in different social conditions. I may say that at first the school teachers were hostile to this new form of school examination, but they soon learned the advantage of it.

Children's Eyesight Forty Years Ago

My Hackney district included good residential quarters in Clapton, artisan dwellings in Homerton, and crowded slum regions in Bethnal Green. In five months of one year I examined 21,893 children aged from 7 to 13. I classified my records as I judged the living conditions of the regions, and found these figures[1]:

Cleanliness	Cases of Eye Disease	Percentage
Above average	19 in 2,174	0·873
Average	134 in 9,463	1·416
Below average	197 in 10,256	1·92
Totals	350 in 21,893	1·59

The first distinctive point I noted in examining my returns was the preponderance of poor sight among the girls. That was shown clearly in Dr. Kerr's L.C.C. report in 1903 of 20,000 children, of whom rather more than half were boys. Of this group 481 boys and 617 girls had only 6/12 vision, and 645 boys and 882 girls failed to reach that mark. More than 57% of the children with poor or bad vision were girls. I reported: "This excessive incidence among the girls was in part due to the fact that the boys played about in the clean wide street [there were no motors then!], sharpening their wits and their physical reactions, while the girls were kept at home to help in domestic duties." And again: "The other part is the nature of the work done in the schools. Girls do finer work, boys do no needlework. So that in vision testing boys had an advantage, for their accommodation muscles were in a better state of tone on account of their outdoor life, and at the same time they are less fatigued by their school work."[2]

Soon I was directed by Dr. Kerr to examine all the children in the blind schools; there were 400 of them. I was shocked to find among the really blind children some who were not blind. These were the highly short-sighted or myopic children. Most of them were not blind at all. At their own distance they could see minute objects, and mentally they were as keen as any school-children. These high myopes were taught to write and read Braille, the blind print of minute humps made in paper. As I watched them (from a place where they did not see me) I saw that they read this Braille with their eyes and not with their fingers. To a person with sight Braille is harder to read than black print of fair size.

I submitted my records of all these children to Dr. Kerr, and suggested that there was good reason to set up special classes for the partly sighted children, for they had no place in the blind school. This was bad for them, and their presence upset the really blind. He agreed with my suggestion. I put the proposition before the International Congress on School Hygiene in 1907, and, happily, Miss Nettie Adler, a member of the Education Committee of the L.C.C., was in the chair at this meeting.[3] She was convinced of the rightness of the suggestion, and in a few months I was given a place where I might start the first of these classes. In a fine school in Camberwell with a wide playground there was a separate small building with two classrooms. This was the first place for these classes. Again, there was at first an unpleasant reaction by the teachers to these "new classes" in their ground, especially as the programme of work I endeavoured to obtain included them. But soon they became as keen on the service as our two special teachers.

The First "Special" Classes

The scheme of work laid down for these classes was as follows[4]: (1) Oral teaching with the normal children for such subjects as could be taught orally. (2) Literary work, such as is necessary for the knowledge of the ordinary means of communication, to be learned without books, pens, or paper, but by the use of blackboards and chalk, the writing to be done free-arm fashion. (3) A full use of every sort of handicraft that would develop attention, method, and skill, with the minimum use of the eyes.

The classrooms must have brilliant daylight; when artificial light was needed all work, other than physical exercises, oral lessons, or games, was suspended. The rooms were fitted all round with blackboards in such a position that they could be used by both teacher and children. Each child had a special desk, the top of which was flat for use in hand work, but could be lifted, giving a blackboard for the child at arm's length on which class-work could be done with chalk. For children in the higher standards some permanent record of work was needed. Exercise books were of a novel pattern, being made up of large sheets of black paper, and the writing was done with white crayon, which gave a record of fair durability but could be washed off if desired. Physical exercises entered largely into the time-table, and attempts were made to associate games with instructional work. For example, large sheets of scenic canvas were supplied to schools that had sufficient floor space, and on these the teachers painted outline maps of different countries, marking out the position of cities, rivers, etc.; the children walked about on these floor maps learning their geography by travelling in imagination. With a teacher of resource there was much interest in this.

The most difficult section of the work was manual training. Whatever work was chosen it did not have to demand fixed attention of the eyes. All sewing was prohibited, but knitting was good. For smaller children paper-folding, stick-laying, felt-weaving in colours, and some knitting were useful. Seniors were taught to do basket work. Boys did bent iron work, and girls were taught cookery and laundry. The teaching of these handiworks was in something like the position of Latin in our own public schools. Latin was later little or no use to us; so with some of these handicrafts. But with each type of child the teaching had the direction of training in care, precision, and control. Later, a long list of suitable occupations (twenty-six forms) was drawn up. The best work was that which allowed the child to be out and about, standing and moving, with a minimum of close-eye attention. Hand work was found to be of great value, for it removed them from living in a world of reading and "book-thinking."

Soon there were many of these classes both in London and in the Provinces. They became very popular in the United

States, and it was from there they got their name of sight-saving classes. Our law recognized only schools for the blind and partially blind; to have called them ".partially-blind schools." would have been disastrous. Parents would have been shocked and hostile. So we called them "myope classes." Most of the children were true myopes, but there was a percentage with scarred eyes from natal defects, from disease after birth, and from injuries. The name served well until we heard "sight-saving classes," and that became an attraction to the parents. In a paper read before the Section of Ophthalmology of the Royal Society of Medicine in 1913[4] I gave a full account of the work of these classes, and it included six pictures of the school work and equipment. As the number of children found to have defective sight—so defective that they were unfit for the normal school and too good for a blind school—increased with years it became difficult to link these classes with the normal school. So that this distinct benefit had to be given up. Schools for myopic children were established in appropriate regions.

Potentialities of Schools for Myopes

Now comes my attempt to answer the main part of the question in the leading article in the *Journal* already referred to. What are the "potentialities of the school for the partially blind"? To my mind the answer to that question is to be found in the records of the variation in the sight of boys and girls in the normal schools. I have given figures showing that the eyesight of girls was at least 10% worse than that of boys. This cannot be explained except by the differences in the lives and work of boys and girls in school years. If this difference be true for "normal" children, it must also be true for children of poor sight, especially for high myopes, whose eyes have an unnaturally soft sclerotic coat and a torn choroid about the optic disk. They have a short point of clear vision; this makes convergence excessive and so squeezes the eyeballs and increases the tendency to an elongation of the eyeglobe, and brings an increase of the myopia.

There is an ancient proverb: "Train up a child in the way he should go, and when he is old he will not depart from it." There can be no doubt that if we teach these partially sighted children how to use their eyes with intelligence they will carry on with the training that we give them after school years. It is difficult to obtain evidence of the effect of this training in school cases or even in hospital cases, for the years through which we see these persons are so few, but I have had ample evidence of the good reaction to training in private patients who have been seen over many years. At one time I was able to collect evidence from the histories of 480 myopes of more than 3D. Of these 183 were engaged in various occupations involving habitual close eye work—e.g., clerks, seamstresses, compositors, etc.—and 297 not so engaged. The comparison was summarized in a table I gave to the Government Committee[5]:

Type of Patient	Number	Breakdowns	Damage to Eyes	Total of Failures
Habitual close eye workers	183 (100%)	.70 (38·2%)	27 (15%)	97 (53%)
Others	297 (100%)	7 (2·4%)	21 (7·06%)	28 (9·4%)
Total percentage in 480	100	16	10	26

The higher total of the second section is accounted for by the number of married women among them, and it includes most of the very high myopes who were unable to do close work. Of the 53% of the close workers whose sight failed at some time of their career no less than 15% sustained permanent damage through loss of an eye. Two persons lost both eyes.

I have had three opportunities of ascertaining the reaction to these sight-saving classes in other and wide areas of the world. In 1930 I crossed Canada to the far west, and in 1935 crossed the United States of America to the Pacific, and in these journeys I saw many eye doctors; all were keen on this part of their work. Again, in 1932 there was a meeting of the Association Internationale de Prophylaxie de la Cécité in Paris. There I read a paper on "Sight-saving Classes,"[6] and the discussion with the ophthalmologists from all countries was most interesting. Those of certain countries on the continent of Europe regretted that the arrangements in the normal schools were not elastic enough to allow a full development of these classes, but they said they were striving to get more of them established.

I therefore hope the sight-saving classes will continue to do their good work for the partially sighted children, for I feel sure that they will save many of our fellow citizens from the loss of their precious sight and from the misery of blindness.

NEW BRIDGE-HEADS FOR ATTACK ON CANCER

EMPIRE CANCER CAMPAIGN REPORT

The twenty-first annual report of the British Empire Cancer Campaign, under the able editorship of Mr. J. P. Lockhart-Mummery, again embodies brief accounts of research work or clinical investigation from about forty hospitals, laboratories, research departments, branch councils, affiliated organizations over-seas, and individual workers. Thanks to the continuing support of the public, notwithstanding so many other claims, the Campaign has been able to allocate nearly £40,000 for research in 1945.

Carcinogenic Agents

Much work proceeded during the last year on the elucidation of the way in which carcinogenic agents act and on the discovery of fresh agents. Thus in the department of pathology, University of Sheffield, progress has been made in explaining the remarkable tumour-producing properties of the compound 2-acetyl aminofluorene. It is now thought probable that the tumours are due to interference with liver function. It has also been possible to localize the carcinogenic action of acetyl aminofluorene to sites not usually affected. Thus both benign and malignant tumours of the thyroid gland have been obtained by the combined action of acetyl aminofluorene and allyl-thiourea.

Several departments have been working on the special properties of benzpyrene. In the cancer research laboratory of the Royal Victoria Infirmary, Newcastle-upon-Tyne, epidermal tumours have been produced in mice by a single application of this substance if the skin has been treated afterwards with some agent, itself non-carcinogenic, which causes epithelial proliferation. The existence of a sensitizing factor in the genesis of tumours is suggested, and it is pointed out that if the same holds good for human pathology, hyperplasia may prove to be a factor of high importance in determining the occurrence of tumours in man.

Work carried out at the Sir William Dunn School of Pathology at Oxford makes it possible to define more closely the relationship between chronic irritation and the onset of cancer. There appears to be little danger of a simple irritant producing a tumour or even a pre-neoplastic lesion by itself, but if a pre-neoplastic lesion has developed, then the subsequent development of a tumour at that site may be facilitated by the action of a non-specific irritant.

An interesting experiment under the auspices of the Marie Curie Hospital indicates that a subline of a high-cancer-incidence strain of mice which had itself lost the power of developing mammary tumours spontaneously may nevertheless transmit this power through the milk factor to a low-cancer strain, showing that the loss of power in the substrain to develop mammary tumours is due not to the milk factor but to a mutation.

Advances in Chemotherapy

At the annual meeting of the Campaign a year ago Prof. E. C. Dodds mentioned Huggins's claim that carcinoma of the prostate gland can in many instances be checked by administration of the synthetic oestrogen known as diethylstilboestrol. It has now been confirmed that such cases can be rendered symptom-free and so maintained for long periods. A report from Middlesex Hospital states that a large series of cases of carcinoma of the prostate are now under treatment with various doses of the three synthetic oestrogens—stilboestrol, hexoestrol, and dienoestrol—and the clinical and *x*-ray picture and other indications are being closely watched.

Some work has also been done at the Royal Cancer Hospital, London, and at the Christie Hospital and Holt Radium Institute, Manchester, on the treatment of cancer of the breast with another synthetic oestrogen, triphenylchlorethylene. Out of 22 cases of late cancer so treated, 10 have shown a significant, though temporary, retardation, or even partial regression of the growth of the tumour, but the initial effect of the treatment passes off comparatively rapidly, and except in one case, which has shown prolonged arrest, the ultimate course of the disease has in no way been altered. In 14 cases of carcinoma of the breast treated with stilboestrol by the same teams, 5 showed similar alterations in the growth and behaviour of the tumour. Mr. Lockhart-Mummery comments that while "the results are not of any immediate practical importance, the fact that a marked response was shown in some cases is, clearly, of the very greatest interest and provides a real incentive to the prosecution of this work."

Radiobiology and Radiotherapy

Some quantitative observations from the Strangeways Laboratory, Cambridge, on the effect of *x* rays and gamma rays of radium on tumours of the cervix uteri and also of the tongue and oral cavity seem to support the opinion given at an earlier stage of the work that the significant biological factor for the successful radiotherapy of these tumours is the capacity of the tumour cells for differentiation. In a series of tumours of the cervix the conclusion was that an increase in dose was not correlated with improvement of results in the differentiating types of growth, but with some improvement in the more anaplastic types.

In cancer of the cervix uteri treated with combined radium and *x* rays, diarrhoea and other intestinal disturbances have been not uncommon, but these have not been observed in cases treated by radium alone, and it is suggested in a report from the Marie Curie Hospital that further investigation should be made before the combined technique as a routine method is held to be justifiable.

The research department at Westminster Hospital reports promising results in radiation treatment of osteoclastomata (dose: 2,000 roentgens).

"The New Alchemy"

A brief note in the report announces that an account is in the press concerning five years' treatment of cancer cases by the million-volt *x*-ray installation at St. Bartholomew's. The scientific committees of the Campaign consider that the time is opportune for an intensified effort in this field. Prof. F. L. Hopwood, at the annual meeting, pointed out also that with the cyclotron every member of the series of natural elements can be disintegrated and transmuted. Quantities of these substances have been given a radio-activity comparable to, or even exceeding, that of the radium family of elements. In addition, beams of neutrons are being produced whose penetration into, and lethal action upon, living matter differ notably from those of *x* rays. Radio-active varieties of such elements as iodine, calcium, phosphorus, iron, and sodium can be introduced, either distributed throughout the whole body or selectively deposited in certain organs, in the form of non-toxic chemical compounds, and there they may effectively irradiate the surrounding tissue. "Thus the alluring prospect is opened up of combining radiation therapy and chemotherapy in a new method of attack on cancer. . . . The new alchemy seems to offer glittering prizes. We must beware lest it also adds to the number of martyrs to science."

Primary Gastric Cancer

Finally, the Clinical Cancer Research Committee of the Campaign presents this year a detailed analysis of 1,405 cases of primary cancer of the stomach.

The proportion of males to females was 3 to 2, and the mean age of onset was 60 in both cases. It was found that 54.5% of the patients had consulted a doctor within the first three months, and that 52% were referred to hospital at once, 13% were kept under symptomatic treatment for periods up to three months, and a further 19% for over four months. The seriousness of the position is shown by the fact that of 241 gastrectomies, only 22% were done while the symptoms were of less than three months' duration, and only 40% of less than six months' duration. Laparotomy was performed in 49% of all the cases, but in only 17% was a radical operation possible, and a palliative operation in only 15%. The survival rate after radical operation in the early stages, before the regional lymph nodes were involved, gave, on the basis of a four-year period of observation, an expectation of life of 65 to 70% of the normal. When only a palliative operation was possible the expectation fell to 40% of the normal. Operation mortalities were as follows:

	Per cent.
Total gastrectomy (20 cases)	90·0
Billroth's operation (27 cases)	25·9
Polya's operation (181 cases)	25·4
Palliative gastrojejunostomy	29·0
Simple exploration	23·0

NEW YEAR HONOURS

(Concluded from p. 23)

We print below the conclusion of the New Year medical Honours List:

O.B.E. (Military Division)

EDMUND HENRY BOTTERELL, Lieut.-Col., R.C.A.M.C.
FRANK PERCIVAL LLOYD, V.D. Lieut.-Col. (Acting Col.), R.C.A.M.C.
JOSEPH ARTHUR MACFARLANE, E.D. Col., R.C.A.M.C.
LORNE CUTHBERT MONTGOMERY, *M.C.*, V.D. Col., R.C.A.M.C.
DONALD ROBERTSON WEBSTER, Acting Surg. Capt., R.C.N.V.R.

O.B.E. (Civil Division)

JOHN BEATTIE DUNLOP, M.B. Post Office Medical Officer, Bradford, Yorkshire.
VICTOR LAURENCE FISHER, M.R.C.S. Senior Surgeon, s.s. *Strathedan*, Peninsular and Oriental Steam Navigation Company.
DONALD MCFARLANE LIVINGSTONE, M.D. Senior Medical Officer, Surrey County Council. For services to Civil Defence.
HAROLD ETTRICK MOORE, M.B. Civilian Adviser in Rehabilitation to the Air Ministry.
MATTHEW BURROW RAY, D.S.O., T.D., M.D., M.R.C.P. Col., Medical Assessor to the Joint War Organization of the British Red Cross Society and Order of St. John.
CAMPBELL KAY STEVENSON, M.D. Medical Superintendent of the Emergency Hospital at Killearn, Stirlingshire.
CHARLES LINDSAY SUTHERLAND, M.D., D.P.H. Chief Medical Officer of the Silicosis Medical Board.
ALEXANDER BOYD WILLIAMSON, T.D., M.D., D.P.H. Medical Officer of Health, Portsmouth. For services to Civil Defence.

M.B.E. (Military Division)

CHARLES HOLLENBERG, Major, R.C.A.M.C.

ASSOCIATION OF VOLUNTARY TEACHING HOSPITALS

At a meeting of nominated representatives of London and Provincial teaching hospitals, held at Westminster Hospital Medical School on Dec. 7, it was agreed to form the Association of Voluntary Teaching Hospitals of Great Britain, the object being to have an organization available which, with its specialized knowledge and experience of teaching hospital problems, will be able to represent those hospitals at all times. It is thought that it will serve a very useful purpose in any planning or negotiations arising out of the Goodenough Committee's report. Among those attending this inaugural meeting were: Dr. H. E. A. Boldero (Middlesex Hospital), Dr. W. Russell Brain (London Hospital), Dr. E. ff. Creed (King's College Hospital), Mr. W. D. Doherty (Guy's Hospital), Mr. G. B. Edwards (University College Hospital), Dr. Hugh Gordon (St. George's Hospital), Dr. F. G. Hobson (Radcliffe Infirmary, Oxford), Prof. T. B. Johnston (Guy's Hospital), Mr. G. H. MacNab (Westminster Hospital), Dr. E. F. Scowen (St. Bartholomew's Hospital), Dr. S. Cochrane Shanks (University College Hospital), Mr. Fauset Welsh (Birmingham United Hospital), Mr. J. M. Wyatt (St. Thomas's Hospital).

Further developments in the plans to deal with nutrition problems in the Colonial Empire are to be financed under the Colonial Development and Welfare Act, 1940, and a free grant of £10,000 has just been sanctioned. A grant of £3,200 to cover preliminary work in connexion with the proposed Colonial Nutrition Organization was made last June. The new scheme is to enable grants to be made for *ad hoc* proposals for interim developments—e.g., engagement of temporary technical staff, training of staff, provision of technical equipment or materials required for experimental work.

Reports of Societies

CHANGES IN MUSCLE AFTER INJURY

At a meeting of the British Orthopaedic Association, held in London on Dec. 15 and 16 under the presidency of Mr. St. J. D. BUXTON, two papers were read on the changes in muscle after injury—the first an experimental study of the vascularization of muscles by Prof. W. E. Le Gros Clark of Oxford, and the second on the changes in human voluntary muscles due to denervation and re-innervation by Miss Ruth Bowden. There were also discussions of papers on recent clinical work on war injuries, including one at Queen Mary's Hospital, Roehampton, on amputations and limb fitting.

Vascularization of Muscles

Prof. LE GROS CLARK said it was well known that most muscles were supplied by two or more main blood vessels, and injected specimens showed quite clearly that their branches effected a number of anastomotic connexions inside the muscle. But such material gave no real indication of the adequacy of these connexions for the establishment of a collateral circulation, or whether the interruption of one of the main vessels (or of one of their intramuscular branches) led to a localized ischaemia which might be severe enough to be of practical importance. These problems had been studied experimentally in rabbits by ligature of blood vessels supplying muscles, the results being assessed partly by histological examination and partly by using a highly diffusible dye—bromophenol blue. This dye rapidly coloured all normal muscles after intravenous injection, and was valuable in assessing the physiological efficiency of the circulation, as it provided an indication of the degree of interchange between the capillaries and muscular tissue, even where a feeble circulation in the main blood vessels might still be present.

The efficiency of the anastomotic connexions varied much in different muscles. In some, such as the tibialis anterior, ligature of one of the vessels of supply led to a sharply defined area of ischaemia. For example, two days after ligature of the lower vessel of supply to the tibialis anterior, intravenous injection of bromophenol blue stained the upper half of the muscle to a normal intensity, but the lower half remained almost entirely unstained, and the boundary between the two areas was sharply defined. The normal vascularization of the lower half of the muscle was not restored for about a week. If both of the main vessels supplying the tibialis anterior were ligatured revascularization was delayed for a fortnight. In experiments in which small steel bearings were shot through the adductor muscles of rabbits at velocities of 250 to 1,000 m. per sec., localized and sharply defined areas of ischaemia were produced as the result of interruption of the muscular vessels (probably associated with some local vascular spasm).

Histological study of the unstained areas showed that most of the muscular tissue had undergone necrosis. The necrotic tissue was removed rapidly by the invasion of granulation tissue with abundant macrophages, and its removal was quickly followed by the regeneration of new muscle fibres. In this way a large part of the damaged muscle appeared to become reconstituted. More experimental work was needed to determine whether this regeneration was more than a temporary phenomenon or whether it led to the formation of functional muscular tissue. The experiments did show, however, that in the muscles of the rabbit there was a remarkable potentiality for muscle regeneration in devascularized tissue, and that in spite of anastomotic connexions the interruption of one vessel of supply to a muscle (or one of its branches) might lead to a relatively extensive and well-defined area of ischaemia lasting for several days.

Changes due to Denervation

Miss RUTH BOWDEN in her paper showed the importance of maintaining the muscular function in units denervated as a result of peripheral nerve injury. In such cases, she said, atrophy was most rapid in the early stages of paralysis, with an increase of connective tissue, associated with Wallerian degeneration in nerve fibres and obliteration of the terminal Schwann tubes and motor end-plates. Eventually, as muscle fibres continued to atrophy, they were replaced by fat and connective tissue. Finally the muscle might resemble tendon. Time was an important factor, for a fairly good degree of functional recovery was possible up to one year after denervation. Nevertheless the atrophy and replacement of connective tissue started from three months onwards. The possibility of reversing the changes in muscle depended on such things as sepsis, age, mobility of the limb, and physiotherapy, as well, of course, as the nature of the lesion in the nerve itself.

The electrical changes in denervated muscle were due not so much to degeneration as to atrophy. The more sluggish response to galvanic stimuli was due to the muscular conduction of the impulse instead of through nerve. It might disappear altogether if atrophy was advanced. Miss Bowden stressed the value of galvanism in maintaining muscular activity and limiting the degree of atrophy; it must, however, be regular and be started as soon as possible after injury. Contractures which might occur in denervated muscle because of the connective-tissue formation could be retarded by physiotherapy, and might be prevented by daily movements throughout the whole range of the joints of the limb. Splinting of paralysed muscles should never maintain complete immobilization.

Early Treatment of War Wounds

In a discussion on early treatment of war wounds, especially those occurring during the invasion of the Continent, Lieut.-Col. E. A. MACNAUGHTON, R.C.A.M.C., described closure and treatment in plaster of ten compound fractures of the femur. He said that provided the immediate primary treatment (surgical excision, blood transfusions, penicillin, and sulphonamides, etc.) had been adequate the thigh wounds were completely closed without drainage at the next stage in treatment, which occurred a week or so afterwards. This was accompanied by accurate reduction of the fracture, and, where required, stainless steel wires or vitallium screws were used in its fixation without prejudice to wound healing. This fracture fixation was, where suitable, done through the existing soft-tissue wound. He emphasized the importance of adequate preparation of the patients for operation by rest (as the patients usually were tired from travelling), replacement of blood loss, further penicillin before and after operation, and avoidance of preliminary examination of wounds in the wards.

Lieut.-Col. R. ZOLLINGER (U.S.A.M.C.) questioned the value of sulphonamide drugs inserted into wounds. This, he felt, was unnecessary if the primary treatment of excision had been adequate. Furthermore, sulphonamides thus inserted into wounds did not penetrate into far crevices, where it was often important to maintain a high concentration of the drug. This could be carried out only by adequate general administration.

Amputations

At Queen Mary's Hospital, Roehampton, Mr. F. G. ST. CLAIR STRANGE read a paper on the amputation stump in health and disease. The amputation stump, he said, must be considered a new and normal organ, upon the perfection of which depended the subsequent health and happiness of the patient. It should be an evenly truncated cone, having the smoothness of skin and scar mobility which followed first-intention healing, and no scar and oedema in the subcutaneous tissues. The operative technique should be planned with precise attention to detail at every stage, so as to achieve a comfortable, efficient, and healthy stump. It must be a plastic as well as an orthopaedic operation. The flaps should be rounded, and should contain deep fascia to retain lymphatic, blood, and nerve supply to the skin. There must be minimum trauma of nerves. Bone and periosteum must be cut at the same level. Careful haemostasis must be followed by artistic skin suture. A neat stump, besides being physiologically sound, gave the surgeon a justifiable sense of aesthetic achievement and, more important, gave the patient a good psychological start. "Dog-ears" and other redundancy must be avoided, the flaps just meeting over the end of the stump.

After operation care must be taken to avoid the development of flexion contractures. There must be a minimum of disturbance of dressings; elastic stump bandaging should be started from the 12th day to shrink the stump without forming a "waist." Non-resisted exercises should be encouraged from the 12th day; progressive resisted exercises did not begin until 3½ weeks after amputation. With a thorough regime stumps were ready for measuring in 4 to 6 weeks' time, and were ready for the artificial limb by the time it was made. On the subject of re-amputation Mr. Strange emphasized the need, in spite of the use of penicillin and sulphonamides, to follow surgical first principles; in other words, the operation should be approached in the same spirit as, for example, a bone graft for an old compound fracture. There must be an aseptic field, and adequate time must be left after the healing of the original sepsis before re-amputation was embarked upon.

Prof. Priorov (Russia) said that in his work plaster was applied to the stumps in order to facilitate transit in cases of primary guillotine amputations in field hospitals. First dressing was never done before the 8th day. Secondly, suture of long skin flaps was frequently done using the sutures through plastic buttons, which could be pulled up gradually until closure was effected. Operative technique was essentially the same as in Great Britain, except that the end of the bone canal was usually tamponed with muscles. Temporary bucket peg-leg prostheses were extensively used. Col. Stark (New Zealand A.M.C.) stated that all their amputations were left open till the 4th or 5th day, and sutured then. They were expected to heal by primary intention. Major Mather Cleveland (U.S.A.M.C.) said American Army surgeons were instructed to carry out circular amputations at the lowest possible level. In most cases these were followed by skin traction within a plaster bucket. The patient was then immediately evacuated to the zone of the interior, where definitive treatment was carried out. Prof. T. P. McMurray asked for caution to be exercised; surgeons should not hastily carry out amputations; even a bad limb of his own might be better to a man than one which was artificial.

During the meeting Major John Charnley, R.A.M.C., demonstrated an adjustable weight-bearing calliper splint designed on the principles of H. O. Thomas and yet available for mass-production in a variety of standard sizes. It had a ring for ischial bearing, which was adjustable within certain limits for differences of thigh circumference, and upright irons adjustable for length by a screw-fitting extension. With a suitable supply of basic parts an hour or two was required for fitting and supplying compared with several weeks for a made-to-measure appliance at present.

MEDICAL AND VETERINARY EDUCATION

A discussion on medical and veterinary education and the parallelism in the preparation for the two professions was held in the Section of Comparative Medicine of the Royal Society of Medicine on Dec. 20, Dr. H. J. Parish, president of the Section, in the chair.

Sir Henry Dale, P.R.S., in introducing the subject, said that the problems of preclinical education in the two professions were largely a matter of common interest; it was in clinical education that the needs of the two disciplines began to diverge, though there were still parallel stretches. The human brain on the one hand and the ruminant stomach on the other had their special physiologies, which could not be covered by any common course; but it must not be forgotten that much of the knowledge of the physiology of the human brain depended on such experiments as Sherrington carried out for many years on the dog, while much knowledge of the physiology of respiration, applicable equally to man and to the domestic animal, was demonstrated much better on the human subject than on any non-cooperating animal.

In both professions, with the rapid progress and expansion of knowledge, it became ever more difficult to compress the necessary instruction within the bounds of a course which would enable the practitioner to start his work before he had passed the term of his intellectual and physical vigour. Sir Henry had been glad to see in the Royal College of Physicians' report that emphasis was laid on the need for jettisoning a good deal which had got embedded in the medical curriculum. In the curriculum of both human and veterinary medicine there was a dichotomy that was likely to make itself increasingly felt. There would inevitably be a cleavage between those who were marked from the outset, by reason of ability, opportunity, or choice, for expert laboratory practice or, perhaps, preventive administration, and those who were trained to apply their knowledge in day-to-day clinical practice at the bedside or in the field. Some separation must be made in the training for these two spheres, otherwise both the man whose career was to be in laboratory research and the man who was to take up general practice would find themselves bogged down with an excess of knowledge that they could not possibly use.

This dichotomy would logically involve a closer association, and perhaps later an actual fusion in training, of those who approached an administrative career in human and in veterinary medicine. In Australia a distinguished pathologist of veterinary training and qualification held for years, with conspicuous success, the post of chief pathologist to one of the leading hospitals in the Dominion. If the history of the researches which had strongly affected the advances in the knowledge of human disease were examined, abundant examples would be found of the reciprocal influence of human and of veterinary physiology and pathology. He mentioned the work of John Hunter, Edward Jenner, Louis Pasteur, Robert Koch, also the much more recent work on dog distemper leading to a more general study of virus infections by his late colleagues Laidlaw and Dunkin. Once it was recognized that there was a special kind of career in experimental physiology and pathology and the study of the requirements of health and the departures leading to disease, he believed that on such a basis work on the human side and on the veterinary side would become so closely linked that they would fuse almost inevitably into a common discipline.

Pre- and Post-graduate Phases

Prof. G. W. Pickering (Secretary, Planning Committee on Medical Education, Royal College of Physicians) said that attempts to reform the curriculum in the past had failed, partly because of natural conservatism, and partly because of absence of agreement as to the shape which reform ought to take. The dilemma in medical and perhaps in veterinary education was the choice between sacrificing on the one hand the educational and on the other the vocational needs of the students. It had been suggested that for the average student university education should cease, and that he should be given a much simpler and more practical training in his craft. He was doubtful, however, whether it was practicable in human society to follow the method of the bee and to select "workers" and "queens." They all knew men who were chosen as "queens" and proved to be second-rate "workers," and men who were made "workers" when well qualified to be "queens." The first step was to divide the curriculum into undergraduate and postgraduate phases. In the postgraduate period particular attention should be paid to vocational training—that is to say, to practical training in the craft of medicine and the requirements of specialisms. It should begin wth a year's resident house appointment, which should be compulsory for all intending to practise medicine. At present it was little wonder, with the multitude of subjects in the ordinary course, if the student became a mere memorizer. Something could be done by planning by the teachers among themselves. The second remedy was the elimination of detail. Above the portal of every medical school should be placed Karl Pearson's words: "The true aim of the teacher should be to impart an appreciation of method and not a knowledge of facts"; though, to be sure, method could not be imparted without imparting some facts. If the curriculum were divided into undergraduate and postgraduate—the first being essential for all, and the second for those with special requirements—a good deal of topographical anatomy, of special pathology and histology, and a number of special medical and surgical procedures could be eliminated from the undergraduate's course. Revision of teaching methods was also needed. The popular teacher to-day was the man who could spoon-feed, but the teacher who was really wanted was the man who made his students think for themselves.

Closer Liaison in the Educational Scheme

Prof. J. B. Buxton (Principal of the Royal Veterinary College) urge that the minimum age of admission to veterinary schools should be 18. The curriculum was in places grossly overcrowded, owing to the mass of factual knowledge which had to be transmitted to the student, rendering the examination a test of memory for detail. Any tendency to specialize in the pregraduate curriculum was to be deprecated. The relative importance of the subjects and their co-ordination should be determined by the needs of general practice. He referred to the desirability of as close a co-operation as possible between his college and the University of London, of which it was a unit. A number of useful contacts socially and in other ways had been made between the students of the College and the other students of the University, especially in the medical schools. The chief impediment was the small number of students who had been induced to read for a university degree. No other professions were so closely connected as the medical and veterinary, and no one would question the desirability of a closer liaison within the framework of the educational scheme. It would not be possible, even if desirable, to teach medical and veterinary students in the same classes, but the desired results could be secured through an administrative system which enabled either the medical or the veterinary student each to make free use of the course of instruction given to the other. By such means their curiosity would be awakened and their natural desire for further information stimulated.

The **President** (Dr. Parish) emphasized the point that teachers should be chosen with some regard to their ability to teach, and not merely for their research status. Lectures were not as profitable as they ought to be; and professors, like ordinary school teachers, might with advantage receive some training in passing on their knowledge to others. The time factor was the main trouble in organizing the medical or veterinary curriculum. It was a very big problem to provide "culture as well as clinics," but he felt that far too much time was being wasted on inferior teaching.

Reform of Teaching

Dr. **Douglas McClean** (Lister Institute) said that excellent principles were laid down in the Goodenough report, but there was failure to apply them in specific recommendations. The committee called for ruthless pruning of the curriculum, but proposed two quite formidable additions to it—psychology and statistics. Medical students were of the most diverse character, aptitude, and ambition. They were given a medley of material, partly in the hope that it would furnish a scientific background and partly in the hope that it would meet some of their instructional needs. The mass of facts served to confuse them and left them without leisure to think. There remained this lamentable hard-and-fast division between the preclinical and clinical phases of education, so that the second M.B. came to be regarded as a *pons asinorum* which had to be passed by accumulating facts which they did not recognize as having any relation to practice in later life. If teachers in the faculty of medicine got together much good could be done by agreement. Preclinical subjects should be presented from the common aspect of the science of human biology. Drastic reductions in the detail of anatomical teaching might be made, but the time saved should not be devoted to adding a whole lot of embryology. Much more time should be given to physiology, biochemistry, and pharmacology. Pathology should be taught much more as a macroscopic science, not a microscopical one. Formal lectures should be cut to the minimum. In all schools there were students who had not a natural aptitude for appreciating generalizations as to scientific methods and yet had qualities likely to make them excellent practitioners. On the other hand, there were those who from the first showed a keen interest in the scientific approach. Should they have two courses—one designed for the scientific study of medicine and the other for producing useful general practitioners? Such dichotomy would lead to a sort of discrimination, one course being regarded as an honours and the other as a pass course. The aim should be a greater elasticity of the present curriculum, and examinations should be planned to allow the students to have a wider choice of subjects.

Dr. **Fred Bullock** (registrar, Royal College of Veterinary Surgeons) said that in veterinary education the teachers and the examiners were brought together and the curriculum was their combined work. Prof. **Edholm** (professor of physiology, Royal Veterinary College) said that with a good teacher a bad curriculum did not matter very much. It was important to make the teaching side of academic work more attractive, and attention should be paid to teaching ability in making appointments. Dr. **John Rickman** suggested that there should be a "job analysis" of a general practitioner's life. He thought that one result of such an analysis which might surprise them would be the amount of time and attention demanded by what might be called social medicine. The results of such an analysis would be useful in directing the education of students. Dr. J. T. **Edwards** remarked that it was a great predecessor of Sir Henry Dale—namely, Sir Joseph Banks, President of the Royal Society in 1778—who directed the movement which founded veterinary education in this country. Dr. E. G. **White** suggested that teachers should prune one another's subjects. In veterinary medicine there should be a basic qualification with as wide a training as possible, but no more specialization than was absolutely necessary, and when this had been gained, as many people as possible should be encouraged to continue their training for a degree after qualification. Dr. W. R. **Wooldridge** said that in medical education they had relinquished what veterinary education still had—namely, the one-portal system. In the veterinary profession there was only one standard of examination, though in fact the examination was held under such difficult circumstances in view of shortage of time and of examiners that it was almost impossible to have a set of examiners to maintain the same standard at every centre. In medicine there had been a very large number of stimulating teachers in the university schools, and as a result a very progressive type of graduate had emerged.

There was a large audience of members and guests at a meeting on Dec. 8 of the Whipps Cross Hospital Medical Society, when Dr. Keith Simpson gave a lecture which he called "Common Sense in the Detection of Crime." Possibly he did not succeed in proving the thesis that his work consists largely of the application of plain common sense, but his address (with lantern slides from his own collection) was enthusiastically received. That the mutilated remains of a woman discovered beneath the hearthstone of a bombed house in Dalston were not those of an air-raid victim (as was at first suggested) was something which could, no doubt, have been established by plain common sense. But the demonstration, despite time and mutilation, of her approximate age and height and then, by means of other characteristics, of her identity and finally that of her murderer and even the manner of her death was a process calling at least for uncommon ability.

The September–October issue of *Industrial Welfare and Personnel Management,* the journal of the Industrial Welfare Society, includes an article on personnel selection in the Canadian Army by Major G. H. Turner, of Canadian Military Headquarters. In 1941 an advisory personnel service was organized (*a*) to describe its requirements not simply in terms of the numbers needed for each of the various duties in each of the Army's units, but in terms of the physical and emotional characteristics, personal attributes, standard of education, and mental level required for each type of work; and (*b*) to describe the non-medical characteristics of soldiers, to assess potentialities for training or employment, making use of both medical and non-medical data, and to make the best possible recommendations for placement. Every man joining the Canadian Army is examined by a medical board and by a specially trained personnel officer. Mental testing is confined to a general classification test, and chief emphasis is placed on a systematic interview. Recommendations for placement are followed up by reports of selection officers at each stage of the soldier's training and at base in theatres of operations, and as time goes on recommendation for training and employment becomes more and more specific. The PULHEMS system of grading was adopted in 1943. It takes its name from the initials of the seven characteristics of a man which are of concern to the Army, and which, taken together as a profile, indicate the kind of work he is fit to do. The points considered are: *P*hysique, *U*pper part of body, *L*ower part of body, *H*earing, *E*yesight, *M*ental ability, *S*tability or emotional make-up. This device provides a handy key to the soldier's physical, mental, and emotional limitations which, when integrated with job specifications, makes possible more appropriate placements and the employment in forward areas of men with minor disabilities not affecting their performance of the particular duties to which they are assigned. The principles involved in this approach are equally applicable to civil employment.

Nova et Vetera

VAN HELMONT: THE 300th ANNIVERSARY OF HIS DEATH

When Jean Baptiste Van Helmont (1579–1644) died, 300 years ago, science and medicine lost a great inaugurator who in spite of credulity and superstition shed much light on medical problems by his discoveries in physiology and his insight into pathology and therapy. These derived just as much from his empirical observations as from opposition to the "humoralism" of the Ancients so stubbornly preserved by his contemporaries.

Van Helmont demonstrated the significance of acid in gastric digestion, which up to his time was attributed to heat and trituration. Acid of a certain nature and at its appropriate place thus performs, in Van Helmont's opinion, an important vital function. It becomes a pathological factor when acting elsewhere, such as in pus formation, notably in empyema. This is interesting in view of modern theories which hold acid reaction of the tissue responsible for leucocytic emigration. Van Helmont denied the existence of such things as the "innate heat and radical humour" which, according to theories current at the time, were cooled by the action of respiration and pulse. In Van Helmont's concept respiration enables an element of the blood to combine with a "ferment" from the air and thus to dispose of a certain "residue" in the venous blood. This material is converted into "volatile salts" and escapes as such through the lungs. The conception is not far removed from our own and was a great advance on the current view.

Van Helmont examined the specific gravity of the urine. He appreciated the high digestive qualities of bile, then regarded as a noxious waste product. He was the first to describe the rhythmic movement of the pylorus and the association of kidney disease with ascites and oedema. He visualized the body as an aggregate of metabolic centres, his "archei." If they perform their function properly, nutritive material will be used up completely. If not, residues are deposited which account for the anatomical changes in diseases. These vary according to the pathogenic agent entering the body from outside—for example, harmful chemical substances inhaled in the mines. The full recognition of these places Van Helmont among the classical describers of occupational diseases, notably silicosis. Van Helmont's therapy was opposed to ancient "constitutional" therapy, which aimed at restoration of the humoral balance. It was directed towards the removal of the harmful exogenous agent; it was "aetiological" therapy. This new concept of diseases as entities determined by the nature of the pathogenic agents and the specific anatomical changes developed *diagnosis* based on the *science* of pathology as against *prognosis* as the main *art* of the physician. Localization of diseases in the organs enabled Van Helmont to unmask the "folly of catarrh"—a then time-honoured way to explain most diseases as the product of a flow of mucus from the brain straight through the skull into nose, mouth, lungs, joints, and muscles.

Hardly any of Van Helmont's works were published during his lifetime. Only twelve years after the publication of his collected works (1648; English translation 1662) Schneider published his book *On Catarrh*, in which he proves again the local origin of mucus. In addition he gave the first description of the mucous membranes. It remains Van Helmont's achievement to have unmasked the "folly of catarrh" and to have established the local origin, in organs and tissues, of most diseases. This was more than 100 years before G. B. Morgagni wrote his book on the *Seats and Causes of Diseases*, which gives the anatomical basis of symptoms rather than of diseases. Van Helmont was therefore in some way in advance of the famous "Father of Pathology." Van Helmont discovered "gas"; this in addition to its chemical notion meaning to him the essence of any concrete body responsible for its specific shape, function, and destination. It represents the force immanent and acting *in* matter as against the usual concept of a "soul" acting from outside *on* passive and inert matter; Van Helmont's concept was taken up by Glisson and Leibniz. Not only this, but the early translations of his work and a multitude of quotations down to the nineteenth century bear witness to Van Helmont's deep influence on contemporaries and posterity.

Correspondence

Nursing and Tuberculosis

SIR,—Can we not come into the open on the question of greater risk to nurses as regards liability to contract tuberculosis? Recent letters in this *Journal* have indicated support for the warnings of the Prophit Survey, tentative and cautious as they were.

I can offer no large figures and percentages, but for years have collected case histories of nurse-patients, and am appalled at the tale they tell and the reiteration of events described. Two facts emerge sharply. So great is the need for nurse labour that diagnostic acuteness is blunted on the part of those who work with them: as regards the girls themselves, there is always the next "exam" looming ahead. So both the employers and employed must struggle on to keep the machine going and to maintain necessary status within it. Further, symptoms when offered are evasive and explainable. When the crash comes the nurse is sent off for treatment, the hospital's rush persists, and it seems to be nobody's business to follow up possible implications.

Replies to inquiries made from two medical superintendents, who receive nurse-patients as part of their normal intake, were revealing. Both were quite clear that the incidence was unduly high. One had expressed his view in a Press letter, which was quoted in the Prophit report as saying that "tiredness does not lead to the *x*-ray room." The other wrote me that "of course" nurses may be expected to go down more frequently than others: they are comparable with front-line soldiers, where heavier casualties must always be expected.

My plea therefore is for a different approach to the whole question of nursing conditions. Admit the thought of front-line service with the corollary of pensions for the disabled and a far higher degree of care for positive health during training. Wards are still being closed for lack of staff because parents have the "horse sense" to realize that, despite better pay, conditions are too arduous.

Until nursing is honestly recognized for what it is—a profession of adventure, of some risk, and of high rewards in service—a lack of recruits may be expected, and is equally deserved.—I am, etc.,

Northwood. ESTHER CARLING.

Mass Radiography

SIR,—Mass radiography is now being used to an ever-increasing extent among the civil population. By this means many cases of pulmonary tuberculosis are being discovered at an earlier stage than would otherwise be possible by waiting for the patient to come to the doctor. For once the doctor is going to the patient first.

Dr. Henderson (Dec. 23, p. 832) says that all that is required to make people come forward for examination is "efficient and attractive propaganda, complete with talking films . . . lecturers to explain to the public what it is all about, and these to go in advance of the unit." If so the propaganda must be much more intense than it is at present. Well-educated people of middle age have spoken to me about mass radiography. They approve of the scheme and understand that other conditions can be detected by this method. Their attitude is, however, that the scheme is all right for young people, but they themselves prefer to remain in ignorance if anything is wrong with them. "Time to worry once they do not feel perfectly well" is the attitude they adopt. Even personal talks often fail to change this point of view.

In connexion with tuberculosis, however, the old well-tried methods of detecting new cases seem to be neglected these days. As a physician in a sanatorium receiving patients from all over the United Kingdom I am frequently being asked by the family of the patient if they are quite safe and have not been infected. Many tuberculosis officers, general practitioners, and consulting physicians fail to tell the patient, once the diagnosis of pulmonary tuberculosis has been made, that his immediate contacts in the same house should be clinically examined and a radiograph taken. In this sanatorium I can call to mind twelve instances in the last year or so where near relatives of in-patients have later developed the disease themselves. Several of these relatives have sought admission, and some have been found to have extensive disease. Had they been examined as contacts when the first case was diagnosed it is almost certain that evidence of the disease in them would have been found also.

Whichever view of adult tuberculosis is taken, either of exogenous or endogenous reinfection, both schools admit that frequent exogenous reinfection can overcome a person's immunity to the disease. Hence as many contacts as possible should be examined both clinically and radiologically. Tuberculosis officers these days are often hard pressed, but the fight against tuberculosis must be an unrelenting one. Even if contact examination be limited to those cases with a positive sputum a good number of cases will be discovered. Thompson, B. C. (*Tubercle*, 1944, **25**, 33), found 4.6% of new cases among 1,817 home contacts. Re-examination should be carried out at least every three months while contact persists, and for two years after this has terminated. Mass radiography must not lead to the neglect of the methods of finding cases which have served us so well in the past.—I am, etc.,

R. GRENVILLE-MATHERS.

Pendyffryn Hall Sanatorium, Penmaenmawr.

Tuberculosis in Kent

SIR,—I am glad that Sir Waldron Smithers (Dec. 23, p. 834) did not write at length on this subject as he threatened, since he has managed to compress into fifty or so lines what must be almost a record in inaccuracies and illogicalities. Why does he pick on the question of provision for the tuberculous if he wishes to carry further the controversy as to the relative merits of voluntary and local authority hospitals? The greater part of the work in this field has long been done by the local authorities. Especially is this true of in-patient facilities. Voluntary effort for the tuberculous is concentrated on provision for out-patients.

One reason for the present shortage of sanatorium beds is that local authorities lack the money to cope adequately with the problem. To provide beds for all the tuberculous patients in Kent who need them would mean raising the rate, if the money were found by present methods. I cannot remember that Sir Waldron at any time advocated higher rates.

The experience of the war has shown once again that national problems must be tackled on a national basis. The E.M.S. scheme may have its defects, but I do not think that even Sir Waldron would suggest that we should have left the care of Service sick to charity. The introduction of allowances for the tuberculous recognizes for the first time the Government's responsibility in the treatment of this disease, which is above all else a social problem. It is only when this recognition is fully implemented and the Treasury accepts financial responsibility for the care of the tuberculous that an adequate and comprehensive service will be developed. The solution must be provided by national finance and planning working harmoniously with the locally elected representatives of the people.

The obstructive bureaucrat, whether he be a legacy from "bumbledom" or merely the conceited dispenser of charity, is as difficult to eradicate as the scabies mite. He is essentially an individualist whose sense of his own importance is stronger than his loyalty to the public. But, like the scabies mite, he will yield to appropriate scientific treatment; in this case a liberal application of live democracy. Meantime we must be on our guard to preserve democratic liberties.—I am, etc.,

St. Mary Cray, Kent. BRIAN H. KIRMAN.

Immediate Repair of the Cervix

SIR,—The correspondence in your columns concerning episiotomy will have served a very useful purpose if only to recall or re-emphasize the importance of an intact perineum after childbirth. Elsewhere (*Clin. J.*, 1944) I have described the perineum as "the flap to the letter-box of life." This may be a little fanciful, but it is certain that a physiologically perfect perineum is essential to a woman's comfort, and, more important, to her happiness.

There is another equally important structure, however, which is much more frequently damaged in labour, and which is as frequently neglected. I refer, of course, to the cervix. It is safe to say that a large proportion of any gynaecological out-patients is composed of the results of a torn cervix—the discharges, the backaches, the trigonitis, the cervical type of dyspareunia, and what not. All of these could be prevented if the cervix was sutured after the third stage of labour. It is easy of access, the damage is obvious, and all the surgical equipment necessary is a masked nasopharynx, a large round-bodied needle, and some fine catgut; even a speculum is often unnecessary. An instant benefit, too, is often apparent, for many of the minor degrees of post-partum haemorrhage are due to bleeding from a torn cervix, and this can be controlled at once by a few simple sutures.

Pointing this out to a general practitioner, he objected: "It's all very well for you consultants to do this in your hospitals and 'posh' nursing homes. In a country cottage it is impossible." Practically, there may be some truth in this. Ideally, there can be no neglect of an important surgical procedure because of expediency. If, however, only those cervices damaged in hospitals and "posh" nursing homes were at once repaired, I assert most confidently that there would be not only an immediate improvement in puerperal morbidity, a greater percentage of healthy parous women, but (who knows?) a lesser incidence of carcinoma of the cervix.—I am, etc.,

MORTIMER REDDINGTON.

High-fat Diet in Diabetes

SIR,—I was much interested in the article on the dietary control of alloxan diabetes by Prof. J. H. Burn and Messrs. Kelsey and Lewis (Dec. 9, p. 752). They rightly point out that the reduction of sugar excretion in alloxan diabetic rats by change over to a high-fat diet could be applied to man with difficulty, since most people are of the opinion that such a procedure would produce ketosis and increase the liability to coma.

I think reference should have been made to the work of Best, C. H., and Hershey, J. M. (*J. Physiol.*, 1932, **75**, 49), with depancreatized dogs. The latter always exhibited a decreased sugar excretion in a phase of generalized weakness and liver failure preceding death. Fat-feeding of their animals precipitated this stage of decreased sugar excretion with, in some cases, a low fasting blood-sugar level, which necessitated a reduction of the previously stabilized dosage of insulin; some depancreatized dogs could, by fat-feeding, tolerate a fairly high calorific diet and no insulin without showing glycosuria or hyperglycaemia for fairly long periods. These latter animals, however, were liable to sudden death and the livers contained large amounts of saturated fatty acids.

In view of this it is possible that a diabetic may appear to be well under control from the point of view of blood-sugar and urine-sugar estimations, but, as in Best and Hershey's dogs, have a fatty degeneration of the liver—an undesirable condition. It may be relevant to mention that I have found that diabetic patients dying in coma almost invariably reveal fatty degeneration of the liver.

It would be interesting if Prof. Burn and his co-workers investigated the fat content of the livers of his rats. If fatty degeneration is found, then I think that a high-fat diet in diabetics should be given with more consideration than merely its effect on blood and urinary sugar.—I am, etc.,

University of Birmingham. RONALD L. BISHTON.

Hypopyon Ulcer

SIR,—It would be highly unfortunate if Dr. F. O. Taylor's report (Dec. 30, p. 868) of the successful treatment of a hypopyon ulcer by sulphathiazole were to give the impression that such a happy result may be expected in all cases. Sulphonamide therapy is a routine part of the treatment of such conditions, but it is only a part, whose effectiveness naturally depends on the sensitivity of the causative organism. To omit, because of sulphonamides, the rest of the medical and, on occasion, surgical treatment would often result in avoidable disaster.

Two points in Dr. Taylor's letter appear to me of especial interest. How was it that no corneal scar remained, and that the eye was "perfectly normal," apart from slight dilatation of the pupil? And, secondly, why was the dilatation "very slight"? Had no mydriatic been employed, or were the posterior synechiae so extensive as to limit its effect?—I am, etc.,

Stratton. R. A. D. CRAWFORD.

Sign for Acute Retrocaecal Appendicitis

SIR,—The meaning of the sign in appendicitis is never complete without reference to the topographical anatomy of the little organ. The situation of an acutely inflamed appendix can nearly always be determined by the pressure method, for it is the inflamed parietal peritoneum in contact with the appendix that serves as a key to its position—a fact that can be proved by doing appendicectomy under local anaesthesia.

As a common experience the tenderness is found over the lower end of the caecum because the mid-inguinal position of the organ is the commonest. Now and again patients are seen with pain in the lower abdomen and tenderness just a little to the right side of the median plane; the appendix is likely to be hanging over the pelvic cavity. Again, in a high retrocaecal type (10 o'clock) the tenderness may be above the anterior superior iliac spine, and this may be even as high as half-way up to the costal margin in the prerenal variety. The accuracy of diagnosis is therefore credited to the teacher of anatomy.—I am, etc.,

Guildford. S. MUNTARBHORN.

Absence of Surgical Shock in Epileptics

SIR,—The case reported by Mr. Grantham-Hill (Dec. 30, p. 867) is an interesting one, but I am sure there are many who would agree that his inferences are unsound. In the first place a crushed limb is often almost painless because of the damage to the nerves interrupting their conduction. It is difficult, therefore, to understand what shock-producing afferent impulses can be present, particularly since experimental stimulation of the proximal end of a divided nerve has been carried out for long periods without producing shock. Secondly, an important element in the case was the damage to the blood supply. The main vessels were divided by the injury, and so the crushed limb was virtually isolated. In consequence there was an absence of the peripheral circulatory factors, such as loss of blood and plasma into the damaged tissues, and, perhaps, absorption of metabolites or products of tissue damage with a toxic action, which have much more evidence to support them as causes of shock than have the nerve impulses. For example, decerebrate animals can be brought to death in profound shock by the infliction of severe injuries to the limbs provided the blood supply to the injured part is not cut off. It is by no means certain, therefore, that the nervous factor is all-important in shock, and the evidence of Mr. Grantham-Hill's case cannot be taken as support for this theory.—I am, etc.,

Oxford. H. HAXTON.

Acute Brachial Radiculitis Improving after Malaria

SIR,—The following case suggests a new method of treatment and may possibly lead to further light being shed on the aetiology of the disease. For permission to report it I am indebted to Dr. R. L. Langley, and to Dr. R. C. Walker, medical superintendent of the hospital.

A well-built previously healthy marine, aged 23, was admitted, seriously ill, on Feb. 21, 1944. He was found to have bronchopneumonia, and responded to treatment with sulphathiazole, recovery being uneventful. On March 12, nineteen days after the onset of illness, he complained of "agonizing" pain across the back of the left shoulder, preventing sleep; there was no constitutional disturbance. The pain lasted a week, then gave way to a dull ache, with "pins and needles" down the outer side of the left arm; and at the same time he found that he was totally unable to lift his arm.

On examination, March 19: Complete paralysis with severe wasting of the left deltoid; reaction of degeneration present. The serratus magnus and spinati (supraspinatus far more than infraspinatus) were affected in lesser degree. There was an area of skin anaesthesia over the area supplied by the circumflex nerve. Other muscles appeared to be unaffected. C.N.S. otherwise normal. Wassermann negative. Diagnosis: "Toxic radiculitis affecting C 5 and 6, a sequela to the pneumonia."

The arm was fixed in an abduction splint and physiotherapy commenced. This resulted after a few weeks in some recovery of the posterior fibres of the deltoid only; only slight recovery of movement (abduction to 45° just possible). Treatment was continued without further improvement until, on Sept. 4, he retired to bed at home with a *relapse of malaria, first contracted in Sicily* in September, 1943. He ran a temperature up to 105° F. on alternate days for ten days before the condition was recognized and controlled with quinine. On getting up he was astonished to find that he could use his left arm to reach up to shelves, comb his hair, etc., without difficulty. On examination, Sept. 25, there was complete voluntary range of movement of the arm, though with persistent weakness of the deltoid and serratus magnus. Wasting of the deltoid still marked; area of anaesthesia unchanged.

The improvement following fortuitous pyretotherapy was dramatic and unquestionable. This finding suggests that pyretotherapy might be worthy of trial in this disease, which in the present state of knowledge may leave severe disablement. If it were found to be effective in further cases, the implication would be that the disease is due to an agent susceptible to raised temperature.

By way of postscript I might add that 18 months ago I saw two infants in a children's ward, in adjacent beds but one, both with empyema. Within a week of each other they developed a sudden flaccid paralysis of the muscles about the shoulder girdle, with wasting, one being on the same side as and the other on the opposite side to the empyema. There was no constitutional disturbance. No other children were affected. The condition was baffling at the time, in the absence of any cases of anterior poliomyelitis in the district. If, as seems likely, they were cases of acute brachial radiculitis they are of interest in raising the question of infectiousness.—I am, etc.,

J. R. EDGE, M.B.,
Menston, near Leeds. Resident Medical Officer,
Highroyds Emergency Hospital

Food Yeast and Artificial Milk

SIR,—The recent statement by Lord Templewood in the House of Lords has one extremely important sentence. He states: "Before we can hope for a revival in Europe the people must be fed." Everybody will agree with this statement, but why does he not include all citizens of the British Empire?

In India the children have been dying in millions for want of food. This want, by lowering their vitality, has made them the prey of serious epidemics. If we hope to see the men and women of India a healthy and happy people it is essential for the children to be given milk. All children need milk, and the giving of milk to school-children (which I first set going in Swansea) has provided ample evidence of its value. If we need a revival in India we must make arrangements to give milk, either fresh or as a good artificial milk. If we want a revolution, then let the children grow up starved and disease-tainted haters of England.

The *Journal* has in the issues for Nov. 18 (p. 668) and Dec. 16 (p. 796) pointed out in two valuable articles a source for the making of an artificial milk. I refer to the growing of "food yeast" in the West Indies. This food yeast contains a protein equal to that of milk, and it can be made up by British chemists into a good artificial milk whereby the Indian children and British can be supplied with good food while the economic condition of the West Indies can be put on a sound footing.—I am, etc.,

Swansea. G. ARBOUR STEPHENS.

Aetiology of Erythema Nodosum

SIR,—In regard to the subject of Prof. Bruce Perry's Bradshaw lecture, published in your issue of Dec. 30, it may be of interest to refer to the fact that erythema nodosum has been recorded in the virus disease lymphopathia venerea, generally in association with "rheumatic" manifestations. References will be found in *A Sixth Venereal Disease* (1933, Baillière, Tindall and Cox, London).—I am, etc.,

London, W.1. HUGH S. STANNUS.

Smallpox Vaccination by the Multiple-pressure Method

SIR,—In my recent paper (*Journal*, Dec. 16, 1944, p. 781) I overlooked an article on "Some Observations on the Immunity and Disability caused by Vaccinia," by S. F. Dudley and P. M. May (*J. Hyg.*, Camb., 1932, **32**, 25), in which the multiple-pressure technique was first reported on in this country. My apologies are due to the writers for this oversight. It is of interest, however, that, although Sir Sheldon Dudley's work was somewhat different in scope from mine, our general conclusions are in agreement.—I am, etc.,

Beckenham, Kent. H. J. PARISH.

Scabies

SIR,—I read Dr. Geffen's article (Dec. 23, p. 825) with much interest, but I must disagree with the statement he makes that "experience shows that home treatment fails in most cases." He has found this the case when he has prescribed benzyl benzoate with full instructions for use in the home.

For the past twelve months I have been giving cases of scabies one treatment of benzyl benzoate. Children have been treated in our cleansing station, but I have given adults pots of benzyl benzoate with written instructions upon how to treat themselves at home. I have been astonished at the very high proportion of cures obtained in this way—something in the nature of 100%. I think the secret of this success lies in the fact that I insist upon the patients' being covered with the preparation a second time immediately after the first application is dry.

I propose during the coming year to adopt the same home treatment for school-children, and I hope that I may obtain the same degree of success.—I am, etc.,

W. F. CORFIELD,
Colchester. Medical Officer of Health.

Medical Demobilization

SIR,—May I be permitted to echo the hope expressed by Dr. J. J. Conybeare (Dec. 2, p. 733) regarding the recommendation of the Central Medical War Committee to the Ministry of Health for the continued recruitment of doctors up to the age of 35. I think Dr. Conybeare "hits the nail on the head" in pointing out the essential differences between the E.M.S. and Service medicine, particularly the exceptional opportunities afforded to holders of appointments under the E.M.S. for obtaining valuable clinical experience in all branches of medicine and surgery and of taking higher qualifications. It is perhaps hardly surprising that so many newly qualified doctors who entered the Services some 4 to 5 years ago are viewing their professional future with some anxiety.

Without wishing to enter the controversy on the merits or otherwise of Service medicine as affecting the individual doctor, I think that after more than five years of war few would disagree with the view that the interchange of doctors between the Services and the E.M.S. would be a good thing for both, and it would seem that length of service in the armed Forces or E.M.S. would be a reasonable basis upon which such interchange might be considered. For those engaged in general practice a similar system of interchange between Service doctors might also be considered on the same basis.

As an aspirant for the Fellowship with five years' Army service I trust I may be forgiven for any prejudices which may be apparent in my letter.—I am, etc.,

"CAPTAIN, R.A.M.C."

Artificial Insemination

SIR,—Whatever may be the ultimate judgment on the moral and ethical issues of artificial insemination, one aspect of the matter would seem to me to have particular relevance to the question, and that is the emotional or psychological effect on the offspring. At what age is he or she to be told? Will he be thrilled to find that he is the product of a planned breeding experiment, or will he feel ashamed? Or will all knowledge of it be kept from him as something about which the less he knows the better?—I am, etc.,

Leicester. T. C. CLARE.

The Death of Burns

SIR,—I observe in the "Nova et Vetera" of the *Journal* of Dec. 30 an interesting note by Dr. S. Watson Smith entitled "The Disease that Killed Robert Burns," in which he states: "The popular belief that he died of drink and rheumatic fever cannot be supported, having no foundation in fact; it is pure fiction." There cannot be many medical men to-day who would support the old and popular opinion that this ill-fated genius died from alcoholism, but I should have thought the whole matter had been fully ventilated some twenty years ago by the late Sir James Crichton-Browne in his book *Burns from a New Point of View*. After an exhaustive survey of the available evidence he states: "It will not, I think, be disputed that Burns died of rheumatic endocarditis, with the origin of which alcohol had nothing to do."—I am, etc.,

Wolverhampton. ARCHD. OGG.

Medico-Legal

A FATAL OVERDOSE OF CARBACHOL

Carbachol, sometimes called "moryl," is a vasodilator and cardiac depressant. In our issue of July 4, 1944 (p. 28), we reported an inquest on Fl. Sergt. J. Simpson, R.A.F., who had died from a massive overdose of moryl given in hospital. The chief reason appeared to be that the manufacturers had without sufficient warning filled the usual ampoules with a quantity of crystals representing 400 times the usual liquid content of an ampoule. The jury found that the overdose had been accidentally given, but added a rider censuring the method of handling the drug at the hospital and the manner of labelling it by the manufacturers. Later the widow sued the Oxford Corporation; Dr. A. Lovas, who had prescribed the drug; Sister Butler, who had administered it; and Messrs. Savory and Moore Ltd., who had supplied it. Mr. Justice Hilbery, in the course of the proceedings, dismissed the corporation, the doctor, and the sister from the case, being satisfied that no evidence of negligence had been given against them. He found that the manufacturers had been packing the drug in crystal form in ampoules and selling it with printed instructions that 1/2 to 1 ampoule was the correct dose, but without a warning that moryl in dry form in an ampoule was not for injection. He held them to have been negligent, and awarded damages against them in the sums of £1,650 under the Fatal Accidents Act and £350 under the Law Reform Act, with costs. He also directed that they should pay the costs of the other defendants. As the doctor and nurse were found not at fault, the court had no opportunity to decide whether the corporation was responsible at law for the results of their actions. Before the decision in Gold *v.* Essex C.C. (1942, 2 K.B. 293), by which a county council was ordered to shoulder the consequences of the negligence of a hospital radiographer, a local authority would probably not, on the facts in the Oxford case, have been held responsible. Since that decision it would almost certainly be held liable if a nurse in its employment gave an injection negligently, and it might even have to pay damages for the negligence of one of its medical staff.

Dr. Lovas's defence was conducted by the London and Counties Medical Protection Society, to whom we are indebted for a report of the action.

A HOSPITAL LOSES A LEGACY

The rules concerning charitable trusts have been a stumbling-block to many charities. Testators without number, having fully intended that some charity shall benefit under their will, have made the gift invalid through some fault of language or disposition. The court will recognize and protect a trust in favour of a person, but not a trust in favour of an institution unless the object of the trust is wholly charitable. The interpretation of the adjective "charitable" is fairly strict: it includes the relief of poverty or sickness, and the furtherance of education or religion, but very little else. Not long ago St. Bartholomew's Hospital lost a large gift through the operation of these rules. Lady Dalziel of Wooler, a great friend and benefactor of Bart's, instituted shortly before her death a "discretionary fund" bearing her name. The capital was some £2,500, and a first charge was the upkeep of the Dalziel of Wooler family mausoleum. The remainder of the income was applicable in the discretion of the governors for the purposes of the hospital. By her will Lady Dalziel increased the discretionary fund by £20,000, subject to the condition that the governors should use the income so far as necessary for the upkeep of the mausoleum and the garden round it and should rebuild it if necessary. If they should fail to carry out this request, the £20,000 was to go to other charities subject to the same condition. The executors, fearing that after duties had been paid they would not have enough left of the estate to pay all the legacies, asked the court to say whether the gift to the hospital was valid.

Mr. Justice Cohen had no doubt that it was not. To begin with—though this was not his reason for rejecting the gift—the original Dalziel of Wooler discretionary fund, with its permanent charge for the upkeep of the mausoleum, looked very much as though it contravened the rule against perpetuities. The law does not like property to be tied up so that it cannot change owners, and so it only allows a moderate restriction on alienation. A testator may tie up money in trust for the benefit of persons living at the time of his death and after their deaths for 21 years, but no longer. Prima facie, there was no means of putting an end to the charge. Counsel for the hospital argued that the charge was purely an internal matter within the hospital, and appeared only in the correspondence between the governors and Lady Dalziel. The judge doubted whether this argument was well founded, but even assuming that it was, the gift would only be good—he pointed out—if the purpose of the discretionary fund of the hospital was wholly charitable. In a general sense he admitted that the purposes of a hospital are necessarily charitable, but the purposes of this fund included the upkeep of the mausoleum. Now the maintenance of a tomb has never been considered a charitable purpose. There have been a good many cases before the court in which a gift with such a condition attached to it has been held valid; but in all of these the condition has imposed only a moral obligation, or the amount involved has been trifling. Here, however, the obligation was meant to be a legal one, for there was a "gift over" to other charities if it was broken. If it had been possible to ascertain how much of the gift would be required for the upkeep of the tomb, the court might have held that the gift of the remaining sum was valid. Here, however, the cost of maintaining the tomb was wholly uncertain. The result was that the hospital lost the £20,000. The judgment gives a very full survey of the tomb cases, and should be studied with close attention by hospital secretaries. They may then be alert to see that the good intentions of their testators are not frustrated by conditions of the kind that wrecked the Dalziel bequest.

A HARD CASE

A woman, intent on her work in a field, was struck dead by an aircraft carelessly flown near the ground. Her husband was partly dependent on her, and sued the pilot. If the same accident had happened before the war he would have had an unquestioned right, as her legal personal representative, to claim on behalf of her estate damages for the results of the pilot's negligence, and for himself damages based on his dependency. Unfortunately for him, he found in his way the Personal Injuries (Emergency Provisions) Act, 1939. This was passed on the first day of the war to compensate persons for war injuries which otherwise might not have given them ground for action. The definition of "war injuries" includes physical injuries caused by the impact of aircraft belonging to His Majesty. The Act expressly rules out the payment of damages for a war injury caused by negligence. Under the Personal Injuries (Civilians) Scheme made under the Act the husband had no right, for he was only partly dependent and not incapable of self-support and in need. Moreover, the scheme makes no provision by which a personal representative may claim compensation on behalf of the estate, nor does it allow funeral expenses. Mr. Justice Charles took the view that as the husband did not benefit under the scheme, it did not deprive him of his ordinary legal remedies, and gave judgment in his favour for £450. The Court of Appeal, however, declared he could not have this.[1] Lord Greene, Master of the Rolls, said that the argument seemed at first sight attractive, that it would be a remarkable thing for Parliament to take away a man's legal rights and give him nothing in exchange, and that to construe the Act in a way which would deprive injured persons of their ordinary rights where the scheme did nothing for them would be a very grave matter. Broadly speaking, he admitted, the court was very reluctant to construe an Act of Parliament as depriving a person of his normal rights. In the present case, however, certain broad considerations indicated the strong probability that the Legislature had meant precisely what it said. It seemed to have taken the view that existing statutes ought not to be regarded as having contemplated injuries arising out of the unusual conditions of war. The scheme of the Act was apparently to lift war injuries right out of the common law and existing legislation and give them special treatment. This seemed to his lordship a very sensible and business-like way of handling a totally unprecedented situation. The widower, however, is not likely to be much consoled by the court's approval of the Act and the Scheme. He might be pardoned for wondering whether his omission from its benefit was due not so much to the wisdom of Parliament as to preoccupation on the part of the draftsman.

Obituary

MICHAEL JAMES NOLAN, L.R.C.P.&S.I.

Dr. M. J. Nolan died on Dec. 27 at Newcastle, Co. Down, his place of retirement, at the age of 85. He had been resident medical superintendent of the Down Mental Hospital, Downpatrick, Northern Ireland, for 42 years, retiring in 1935.

He was educated at Crescent College, Limerick, his native town, and at the Royal College of Surgeons in Ireland. After qualifying he was for some five years in general practice in Limerick, and during part of that time deputized for the superintendent of Limerick Asylum during his absence from duty. This was the beginning of Dr. Nolan's life-long attachment to psychological medicine, and in 1888 he was appointed deputy resident medical superintendent to the Richmond Asylum, Dublin, now Grangegorman Mental Hospital, where he remained until his appointment as resident medical superintendent to Down Mental Hospital in 1893. During his 42 years there his hospital gradually became known as one of the foremost in Ireland, and this position was of Dr. Nolan's making, for he was in the old tradition of medical superintendents in the grand manner, and ran his institution with complete personal supervision of every detail.

When he first became associated with psychological medicine, little scientific work was done in the Irish mental hospitals, and few papers were published by Irish psychiatrists. Dr. Nolan changed all that, as he changed many other things: over all his professional life a series of papers on his specialty flowed from his pen, and he was co-editor of the seventh edition of the *Handbook for Mental Nurses*. He took a great part in what might be called medico-political work, and the application of the Asylums Officers' Superannuation Act to Ireland was largely due to him.

Many honours came his way. He was, for example, president of the Royal Medico-Psychological Association in 1924–5, and president of the Ulster Medical Society 1926–7, a Fellow of the Royal Society of Medicine, and a Fellow of the Royal Academy of Medicine in Ireland. He was a J.P. and a member of the executive council of the Magistrates' Association of Northern Ireland.

His interests were wide and included gardening and archaeology. His commanding, bearded presence made an instant impression, and a slight stutter was turned by him into an asset which told to effect in many of his anecdotes, which he was an adept in using to clinch a point. His wit and humour never deserted him, not even when he was afflicted with blindness over which his great courage enabled him to triumph, and later a paralysis was surmounted in the same fashion.

D. L.

W. ERNEST A. WORLEY, M.R.C.S.

In our issue of the *Supplement* of Dec. 30 we recorded the retirement after 25 years' service of Dr. Ernest Worley from the office of honorary secretary of the City Division of the B.M.A. and the presentation to him by his colleagues of a cheque and an illuminated address. We deeply regret to announce that he died on Dec. 28. He was a Bart's student and took his M.R.C.S., L.R.C.P. in 1899. He was temporary captain, R.A.M.C., in the last war. He joined the Association in 1911 and began his active work for his Division in 1921. He was chairman of the Division in 1931 and represented it at the A.R.M. on five occasions; was a member of Council from 1927 to 1933 and of several of its committees; and was honorary secretary of the Centenary Meeting, London, 1932.

Dr. ALFRED COX writes:

The death of Dr. Ernest Worley removes an ardent and devoted worker for the B.M.A. His loss will be most deeply felt in the City Division, of which he had been the very life and soul, as well as the secretary, for 25 years. He was one of those who never sought the limelight and made a hobby of B.M.A. work. I remember visits to the City Division, when I was in office, which convinced me, if I had needed any convincing, that so long as Worley was in charge the Division would be an active one. How he managed to conduct an active practice and at the same time devote so much energy to the Association is a mystery which I have never been able to solve except by recourse to the old saying that "a man can always find time to do something which he really wants to do." His finest achievement was when he cheerfully accepted the heavy responsibilities of the honorary secretaryship of the London Annual Meeting of 1932, and every day during the long period of preparation he could be seen at B.M.A. House. No detail was too small for his attention. I have been told that at the historic centennial dinner at the Albert Hall, where some 2,100 people sat down to dine, Worley personally inspected every table ticket to see that all the guests were rightly placed. In paying this affectionate tribute to an old friend and fellow worker I must not forget (he never forgot) the devoted labours of his wife—not only socially but in the day-to-day work of the City Division.

---

[1] Billings v. Reed, (1944) 2 All E.R. 415.

The death took place on Nov. 28 of Dr. **TIMOTHY HOWELL DAVIES**, Pentrepoth Road, Morriston, Swansea. He was a member of a very well-known and old Morriston family, being the eldest son of the late James Davies, a founder director of the Morriston and Midland Tinplate Co. Ltd. Dr. Davies, popularly known as Tim, was educated at Arnold's College, Swansea, and, on entering the Middlesex Hospital, studied under, among others, the late Sir John Bland-Sutton. He qualified M.R.C.S., L.R.C.P. in 1907, and practised in Morriston up to the date of his death. Dr. Davies had intended retiring in 1939, but in view of the calls made on the medical profession continued in practice until his death. He was an ardent Welshman and an authority on the history of old Morriston.

The death occurred in Darlington on Dec. 15, in sudden and tragic circumstances, of **GEORGE ALEXANDER DAWSON**, medical officer of health for Darlington. A Belfast graduate (M.D., B.Ch., D.P.H.), he was formerly assistant M.O.H. for Oldham, and was appointed to the same post in Darlington in 1925, succeeding shortly thereafter his chief, who was killed motoring. Dr. Dawson was president of the Northern Branch of the Society of Medical Officers of Health in 1930–1, chairman of the Darlington Division of the B.M.A. in 1932, elected a Fellow of the Royal Sanitary Institute in 1935, chairman of the district council of Toc H, a past president of Rotary, and a past master in Freemasonry. He was a forceful personality with an unbounded capacity for work. He died a bachelor, 46 years of age, and public expression of loss has been wide and marked.

The death occurred at Harrogate on Dec. 16 after a brief illness of **HAROLD DOBSON PICKLES**, *M.C.*, M.R.C.S., L.R.C.P., at the early age of 53. He was the son of the late Dr. J. J. Pickles of Leeds and received his medical education at the Leeds Medical School, qualifying in 1915 and immediately joining the R.A.M.C. He served in France, being mentioned in dispatches and gaining the Military Cross, and settled in practice in Leeds in 1919. He subsequently practised at Westerham in Kent, but returned to his own county, to Masham, where he was also M.O.H. Dr. Pickles was one of the best type of general practitioner, at all times placing the interests of his patients before his own comfort and convenience, despite the handicap of increasing deafness and of a heart damaged by rheumatism in youth. He leaves a widow, one daughter, and two sons.

Dr. **JAMES GRIFFITHS MACASKIE**, formerly of Bambrugh, died on Jan. 3 at Seahouses, Northumberland, aged 89. He was born at Berwick-on-Tweed, went to school at Newcastle, and studied medicine at Edinburgh. He qualified L.R.C.P.&S.Ed. in 1878, took the D.P.H. in 1890, and joined the B.M.A. in 1904. He retired from active woik in 1927 after 47 years' practice at Bambrugh, where he won the respect and esteem of all classes. Dr. Macaskie was for 44 years Poor Law medical officer and for 33 years M.O.H. for the Belford Rural District Council. In 1924 he was made a Justice of the Peace. His three sons all became members of the medical profession.

Dr. **JEROME JOHN O'MULLANE** of Plumstead High Street, S.E., died at the age of 52 at the London Clinic on Jan. 2. He graduated from University College, Cork, as M.B., B.Ch., and B.A.O. of the National University of Ireland in 1916, and served as house-surgeon at the West London Hospital. Dr. O'Mullane joined the British Medical Association in 1925. Although in bad health for some time past he was an energetic worker and an enthusiastic reader of current medical literature. His death will be a great loss to Woolwich.

Dr. **GUSTAV SINGER**, formerly emeritus professor of internal medicine at Vienna and an Austrian privy councillor, died in Guy's Hospital after a short illness at the beginning of December. He was especially interested in gastro-enterology, and in January, 1938, delivered a lecture in this country on functional diseases of the intestines. This was afterwards published by the Oxford Press as a monograph which we noticed in the *Journal* of May 25, 1940 (p. 854). Gustav Singer was a friend of the late Sir Arthur Hurst, who had much admiration for his work.

The following well-known medical men have died abroad: Dr. **FREDERIC WILLIAM SCHLUTZ**, chairman of the department of paediatrics of Chicago University, aged 63; and Dr. **JOELLE CORNELIUS HIBBERT**, clinical instructor in obstetrics at Boston University School of Medicine, aged 51.

Medical Notes in Parliament

G.M.C. Elections

On Dec. 14 Sir **HAROLD WEBBE** moved that the General Medical Council (Temporary Provisions) Order, 1944, a copy of which was presented on Dec. 5, should be annulled. He said he was told that the *Medical Register* might well contain as many as 44,000 names. An election was not an impossible business and was certainly not much more difficult than holding an ordinary by-election. It might be argued that in this case the council could not get a proper election because so many of the electors—the medical practitioners—were away serving the country in the Forces. He was sure that the Government would not use that argument, because the House had already decided that the absence of all these doctors in the Forces was no valid reason for postponing legislation which fundamentally affected the whole medical service and drastically and vitally affected the future of every one of them.

Mr. **ATTLEE**, in reply, agreed that, wherever we could and wherever it was feasible, we should restore the right of elections. These postponements were not something which was imposed on various bodies by the Government, but was done at the request of those bodies. It was necessary, however, to see that they did not perpetuate themselves unnecessarily. These Orders were not granted as a matter of course; they were examined very carefully. The G.M.C. had 39 members, of which 32 were nominated with the advice of the Privy Council or chosen by certain colleges and universities, who might be held to be mainly indirect representatives of the medical profession. Seven were elected by medical practitioners. The latest available figures showed that the electorate numbered somewhere about 65,000. The strain on the medical profession at the present time was immense. The strain on the G.M.C. had been pretty heavy. People did not know where a large proportion of the 65,000 doctors were. A large proportion were over-seas. A great many of the others had been moved about the country according to the exigencies of the war. Even in normal times this election was fairly costly. A single election cost about £500 and sometimes there had to be two or three a year. The staff of the council had been very greatly reduced. It would be very difficult and involve an unnecessary amount of time if the election papers were to reach all members of the profession.

Dr. **RUSSELL THOMAS** said he would like to emphasize the fact that Mr. Attlee, on behalf of the Government, had made it perfectly clear that the medical profession could not be expected to come to any decision on any matter at the present time. He was grateful to him for making his decision so clear.

The motion was, by leave, withdrawn.

Medical Research Expenditure

In a written answer on Dec. 21 to Sir Ernest Graham-Little, Mr. **ATTLEE** said it was impossible to give a comprehensive estimate of current annual expenditure on medical research in this country. Investigations were financed not only out of public moneys but also by private funds administered by universities and hospitals and by independent research institutes and organizations. Only a relatively small part of the total expenditure from funds of private origin was controlled by the Medical Research Council. The expenditure of the Medical Research Council amounted to about £290,000 in 1944–5. Of this, £250,000 was provided by the Parliamentary grant-in-aid and the remainder from contributions and repayments from various Government Departments and sundry credits. The expenditure directly allotted to medical research through other Government channels was at present about £100,000 a year, mainly on special investigations by the Services into war problems. This took no account of research undertaken by members of the medical services with the armed Forces and otherwise, in addition to other duties for which they were primarily employed. Nor did it take account of research done by institutions in receipt of Government grants for mainly educational work.

Demobilization

Mr. **BEVIN** stated on Dec. 21 that the scheme outlined in the White Paper on the reallocation of man-power between the armed Forces and civilian employment during any interim period between the defeat of Germany and the defeat of Japan (Cmd. 6548) applied to medical officers in the same way as to other members of the Forces. There was provision in para. 12 of the White Paper for the release in Class B—i.e., out of age and service order—of a limited number of individuals on applications made through Government Departments in accordance with the existing arrangements. In the case of medical officers these arrangements provided for recommendations to be made by the Central Medical War Committee.

Promotion in P.O.W. Camps.—Sir James Grigg informed Sir George Elliston on Dec. 13 that he did not consider special arrangements should be made to permit normal opportunities of promotion for medical and dental officers of the R.A.M.C. detained in enemy prisoner-of-war camps for the care of British prisoners. Time promotion was carried out under the normal rules for all officers who were prisoners of war.

Midwives in the Services.—Mr. Willink told Mr. Storey on Dec. 14 that he had considered the recommendations sent to him last August by the Northern Branch of the B.M.A. that trained midwives should no longer be accepted for the Services or industry and that those already accepted should be released or directed to their proper work. He had consulted the Minister of Labour and National Service and had communicated with the B.M.A. The nursing services of the Crown had, since May, 1943, been precluded from recruiting practising or newly qualified midwives or midwives with recent experience. Similarly as regards industrial nursing, experienced or practising midwives were not admitted to posts unless they were immobile and there was no prospect of using their services in local midwifery work. A review of all qualified midwives already employed in industry had already been made. Those with good or recent experience were withdrawn, though there was sometimes a little delay. In view of operational needs and the fact that any midwives now in the Services must have qualified some time ago and be scattered over the world, he could not press the Service Departments to release them at present.

Notes in Brief

It is expected that the factory at Speke, Liverpool, for production of penicillin will be completed by the late spring of 1945.

It is hoped that in 1945 8,000 acres in India will be under cinchona. Before the war 4,500 acres were planted with cinchona. The supply of quinine is unequal to the demand, but synthetic antimalarial drugs are reaching India in large quantities.

Since the increase in cash allowances to fighting men's children, issues at cheap rates of fruit juices and cod-liver oil to children have declined by 15% and 25% respectively comparing August and September with the previous six-months average. There is no evidence that families not entitled to free supplies cannot meet this expenditure. Issues of milk free or at cheap rates have not declined.

The Services

Major-Gen. N. Cantlie, M.C., late R.A.M.C., has been appointed Honorary Physician to the King in succession to Col. (Local Brig.) S. Smith, late R.A.M.C. (ret.).

Capts. C. T. A. Burgess and A. A. Grierson and Lieut. O. Gray, R.A.M.C., have been appointed M.B.E. (Military Division) in recognition of gallant conduct in carrying out hazardous work in a very brave manner.

Temp. Surg. Lieut. I. R. W. Alexander, R.N.V.R., has been mentioned in dispatches. This name appears in a list of awards for gallantry or good services in the last six months or more of war in certain of H.M. ships.

Majors E. L. Elliott, 4th Btn. Buckinghamshire Home Guard, N. J. Cochran, 8th Btn. Staffordshire Home Guard, P. W. Edwards, 16th Btn. Staffordshire Home Guard, and A. W. Marrison, 3rd Lindsey Btn. Home Guard, have been appointed M.B.E. (Military Division) in recognition of meritorious service in the Home Guard.

Major C. M. Russell, 32nd Btn. County of London Home Guard, has been appointed M.B.E. (Military Division) in recognition of meritorious service in the Home Guard.

CASUALTIES IN THE MEDICAL SERVICES

Died on active service.—Lieut.-Col. Ernest F. Waldemar Grellier, R.A.M.C.

Wounded.—War Subs. Capts. H. I. C. Bowie and J. C. D. Mellor, R.A.M.C.

Wounded or injured.—Temp. Surg. Lieut. K. V. J. Kearney, R.N.V.R.

DEATHS IN THE SERVICES

Surg. Rear-Adml. Thomas Creaser, who died on Dec. 15, graduated in medicine at Dublin University in 1904 and proceeded M.D. three years later. After holding house appointments he entered the Navy in 1907. He took part in the Battle of Jutland when serving in H.M.S. *Boadicea*, and was professor of clinical pathology at the R.N. Medical School, Greenwich, in 1924–7; then for two years he held the post of squadron medical officer of the Battle-cruiser Squadron in H.M.S. *Hood*. He was in charge of the R.N. Hospital at Haslar from 1937 until the end of 1940. For more than a year before his retirement Adml. Creaser was Honorary Physician to the King.

Medical News

The Eugenics Society has arranged a meeting at the rooms of the Royal Society, Burlington House, Piccadilly, W., on Tuesday, Jan. 16, at 5 o'clock, when Mr. Cecil Binney will speak on "Eugenics and Criminal Law." All interested in the subject are invited to attend.

The following meetings of the British Institute of Radiology have been arranged for January and will take place in the Reid-Knox Hall, 32, Welbeck Street, London, W. Thursday, Jan. 18, at 8 p.m., ordinary meeting followed by a "Symposium on Clinical Photography." Speakers: Mr. T. Pomfret Kilner, Mr. Stevenson Clark, Miss Shaw, Mr. F. W. Coppin. Friday, Jan. 19, at 5 p.m., meeting of medical members.

The Diagnosis Section of the Faculty of Radiologists will hold a meeting on Friday, Jan. 19, at 2.15 p.m. at the Royal College of Surgeons, Lincoln's Inn Fields, when Surg. Rear-Adml. Robert Milne is to read a paper on "Avascular Necrosis with Joint Trouble in Caisson Workers."

At a general meeting of the Tuberculosis Association to be held at 26, Portland Place, London, W., on Friday next, Jan. 19, at 3.30 p.m., papers will be read by Dr. E. T. Fletcher on ankylosing spondylitis and tuberculosis; by Dr. R. B. Illing on the prognosis of chronic miliary tuberculosis in children; and by Dr. M. C Wilkinson on the nature of resistance in tuberculosis.

The Food Education Society (29, Gordon Square, W.C.1) announces that Dame Louise McIlroy, M.D., will lecture on "Food and Maternal Morbidity and Mortality," on Jan. 22, at 2.30 p.m., at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.

A meeting of the Scottish Group of the Association of Industrial Medical Officers will be held on Wednesday, Jan. 24, at 3 p.m prompt in the Institute of Hygiene, University of Glasgow. The business of the meeting, at which Dr. H. M. Roberts will preside, will be general, and all interested in industry are invited.

The British Federation of Social Workers has arranged six lectures on "The Background to Health," to be given in Alliance Hall, Palmer Street, Westminster, S.W., on Wednesdays, Jan. 24 and 31, Feb. 14 and 28, and March 14 and 28. The January lectures will be by Prof. J. M. Mackintosh, on "What is Social Medicine?" and Mr. R. Watson-Jones, on "Rehabilitation." Application for tickets (1s. 6d. each lecture, 7s. 6d. for the course) should be made to the hon. secretary of the Federation (5, Victoria Street, S.W.1).

A meeting of the Association of Industrial Medical Officers will be held in Birmingham on Thursday and Friday, Jan. 25 and 26. Programme: Thursday, 8.30 p.m., business meeting, Queen's Hotel, New Street Station. Friday, 9.30 a.m., organized visits to iron foundries in the area. 2.30 p.m. at gymnasium of the Birmingham Accident Hospital, Bath Row, papers will be read by: (1) a representative of the Council of the Iron Foundries Association, on "Iron Foundries"; (2) Dr. G. F. Keatinge, medical officer, The Butterley Co. Ltd., Derby, "Health in Iron Foundries." After the papers there will be a discussion.

The Association of Clinical Pathologists will hold a meeting in London on Friday and Saturday, Jan. 26 and 27, at 9.30 a.m. at the Westminster Hospital School of Medicine.

The Royal Sanitary Institute announces the following sessional meetings: Jan. 27, at 10.30 a.m. in the Council Chamber, Town Hall, Sheffield; papers on "Some Aspects of Water Supply," by Mr. J. Noel Wood, general manager and engineer, Sheffield Corporation Waterworks; and "A Review of the Treatment of Cerebrospinal Fever," by Dr. J. M. Kennedy, medical superintendent, Lodge Moor Hospital, Sheffield. Feb. 14, at 2.30 p.m. at the Institute (90, Buckingham Palace Road, S.W.1), papers on "Ventilation of Dwellings," by Dr. T. Bedford, of the Industrial Health Research Board, and Dr. J. Greenwood Wilson, M.O.H. Cardiff. March 2, at 3 p.m. at the Public Library, Turners Hill, Cheshunt, papers on "Post-War Housing Requirements."

Mr. Desmond MacCarthy, LL.D., will deliver the Lloyd Roberts Lecture at 3 p.m. on Tuesday, Jan. 30, at the Royal College of Physicians, Pall Mall East, S.W. Subject: "Psychology in Literature."

Doctors will shortly receive a copy of the Ministry of Food's new booklet (M.E.D.2), which supersedes earlier issues, on special rations and allowances to invalids and persons requiring special diets Further copies may be obtained on application to the Ministry of Food, Welfare (Foods) Branch, Mount Stewart Hotel, Colwyn Bay.

The Ministry of Food announces that dried bananas are available, in amounts up to 14 lb. a month, for adult patients with steatorrhoea. Applications should be made to the local Food Office, accompanied by proof that steatorrhoea is present, such proof including an analysis of the patient's stools for fat.

No. 51

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Dec. 23.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1944 (a)	1944 (b)	1944 (c)	1944 (d)	1944 (e)	1943 (Corresponding Week) (a)	1943 (b)	1943 (c)	1943 (d)	1943 (e)

Rate per 1,000 total births (including stillborn)			29					41		

---

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* infectious diseases were generally less prevalent. Last week's notifications fell by the following figures: measles 552, scarlet fever 84, dysentery 28, whooping-cough 26.

There was little change in the local trends of scarlet fever and whooping-cough. Lancashire had 24 fewer cases of diphtheria than last week, but Yorks West Riding had 12 more. The fall in measles ends a continuous rise of fifteen weeks: in the counties notifications dropped by the following numbers: Lancashire 240, Durham 120, Wiltshire 86, Cumberland 77, Northumberland 53, Middlesex 51; on the other hand, the following increases were reported: Warwickshire 105, Yorks West Riding 86, Nottinghamshire 56, London 49. The incidence of dysentery is now at less than half the total of a month ago. The chief centres of infection were London 44, Lancashire 34, Gloucestershire 10, and Yorks West Riding 10, the remaining cases being recorded from twenty-eight counties.

In *Scotland* all the common infectious diseases of childhood were less prevalent—measles by 189 cases, scarlet fever by 79, diphtheria by 25, and whooping-cough by 17. For the second week a relatively large rise occurred in the notifications of dysentery, due to an outbreak in Lanark County, where the cases mounted from 13 to 61. The incidence of dysentery fell in most areas, and the only other large centre of infection was Glasgow 27.

In *Northern Ireland* notifications of scarlet fever continued to fall, the total now being 44, compared with 117 at the end of November. The incidence of measles is dropping more slowly, 248 cases being recorded, compared with 273 four weeks ago.

Infectious Diseases during 1944

The chief features of the returns of England and Wales during the past year were the high level of dysentery and the low level of diphtheria. The notifications of dysentery have steadily risen throughout the war, and this disease has now become endemic in most of the country. The notifications of diphtheria have steadily fallen since 1941, and the total for 1944 was the lowest ever recorded. The lowest number of cases since the war was also recorded for measles, acute pneumonia, cerebrospinal fever, and enteric fever. A comparison of the war years is given in the following table:

Notifications of Infectious Diseases in England and Wales during the War

	1940	1941	1942	1943	1944
Scarlet fever	65,573	59,111	84,932	116,217	93,801
Whooping-cough ..	53,403	171,406	65,563	95,859	93,107
Diphtheria	46,683	51,091	42,318	35,944	29,446
Measles	407,908	406,507	285,300	374,198	117,437
Acute pneumonia ..	47,712	50,514	42,487	52,225	38,175
Cerebrospinal fever ..	12,791	11,119	6,089	3,380	2,883
Dysentery	2,843	6,597	7,177	7,772	10,150
Enteric (paratyphoid and typhoid)	2,824	4,703	887	707	536

Notifications of cerebrospinal fever, which fell rapidly after the large outbreak at the beginning of the war, have improved only slightly on the 1943 level and are now two or three times the pre-war figure. Figures for deaths from influenza are at present available only for the large towns. The rather light mortality from influenza in the past year was due to the unusually early appearance of the epidemic in the late autumn of 1943, which increased the deaths of 1943 by over 4,000.

Deaths from Influenza and from Diarrhoea and Enteritis, and Infant Mortality Rate, in the 126 Great Towns

	1940	1941	1942	1943	1944
Influenza deaths	5,510	2,993	1,544	6,280	1,744
Infant mortality rate ..	62	71	58	58	52
Diarrhoea and enteritis deaths under 2 years	1,754	1,785	2,268	2,582	2,553

The figure for infant mortality is the lowest for the war years, despite the increasing number of deaths due to diarrhoea and enteritis.

Week Ending December 30

The returns of infectious diseases in England and Wales during the week included: scarlet fever 1,512, whooping-cough 1,179, diphtheria 446, measles 8,870, acute pneumonia 812, cerebrospinal fever 38, dysentery 123, paratyphoid 6, typhoid 4

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Severe Seborrhoea

Q.—*During the past 6 to 8 weeks I have been treating four patients for severe seborrhoea. No treatment, however, seems to improve the cases. The scalps are reddened and slightly irritable, with a great weeping of sebum. Consequently the scalp is covered with an abundance of scales. Added to this is a great loss of hair with threatened alopecia. I would appreciate advice.*

A.—The writer describes an eczematized seborrhoea, a sensitive condition which is unable to tolerate 10% sulphur. If circumstances permit the hair should be clipped short, a boric-starch poultice applied for 6 hours to clear up the mess, followed by a wet dressing such as lead-glycerin lotion, later disinfecting with H_2O_2 (5 vols.), oily calamine lotion being subsequently applied. When the eczema has been controlled, more active remedies can be tried very cautiously, probably avoiding sulphur, even the customary 2% concentration.

Allergy to Milk

Q.—*My son, aged 11, strong and healthy, has lately developed chronic nasal catarrh, apparently coincident with his drinking a lot of milk: until lately he did not like milk. His mother, during his pregnancy, developed pernicious anaemia of pregnancy, which was controlled by liver injections. During her second pregnancy she became sensitive to the liver. Is there any connexion in the sense that this catarrh may possibly be of an allergic type, and if so, what diet for such a growing boy could be advised?*

A.—Chronic nasal catarrh is an ill-defined entity. Congestion of the nasal mucosa may be due to septal deviation, sinus infection, adenoid vegetation, or constant exposure to a damp or dusty atmosphere. Before ascribing it to drinking milk one would demand more typical allergic symptoms, such as attacks of sneezing, lacrimation, and rhinorrhoea, and an excess of eosinophil leucocytes in films of the blood and nasal secretion. Other symptoms of food allergy, such as abdominal pain and diarrhoea, might also be expected. Furthermore, an allergic rhinitis should disappear when the allergen is removed and reappear when it is returned to the diet. In practice an elimination test is not easy to perform as milk comes into the composition of so many foods—not only milk, cream, butter, and cheese, but also bread, pastries, and margarine. Milk-free diets for the diagnosis of milk allergy may be obtained from A. H. Rowe's book, *Food Allergy*, London, 1931. Quite frankly, then, the diagnosis of milk allergy does not seem to be well established in this case, and even if it were one would conclude that in so far as the symptoms are mild and there is no alimentary upset it would be better to put up with the nasal catarrh than with a milk-free diet. Such diets are difficult to arrange in wartime, and introduce the danger of shortages of biological protein, vitamin D, calcium, etc. A compromise would be to let the boy drink goat's milk or well-boiled cow's milk. It is not easy to see any connexion between the boy's illness and his mother's. The development of sensitivity to liver given by injection does not appear to have any clear relation to spontaneous food allergy.

Effects of Sexual Continence

Q.—*Is it known what happens to the semen when it is retained in the body? Leaving aside the psychological effects, it is evident that different physiological adjustments must take place in the completely continent individual from those that occur in the man who lives a life of regular elimination of semen. Is there any evidence that continued or temporary retention causes any bodily ill effects?*

A.—Not much is known about this subject, but I do not believe that there is any evidence that continued voluntary abstinence causes any bodily ill effects. Not infrequently intermittent, spontaneous, and involuntary emissions occur during sleep in otherwise completely continent individuals. The ejaculation of semen, which is stored in the seminal vesicles, is usually a stimulus to further production of semen by the testes. Assuming that the semen stored in the seminal vesicles were retained indefinitely, and not spontaneously emitted from time to time, it might undergo degenerative changes, but it is doubtful (*a*) whether this occurs; or (*b*) if it does occur, whether it has any harmful effect on the body.

Psychological results of attempted complete continence are a different matter, but more often than not it is the psychological make-up of the individual which determines whether or not he will attempt to be completely continent. In other words, attempted voluntary continence is only one aspect of the whole picture.

Adrenaline Injections

Q.—*(a) Are there any ill effects caused by prolonged injections of adrenaline for asthma? (b) Is an injection of 1/2 c.cm. (1-1,000) every 5 or 6 hours, for some days if necessary, to control attacks, harmful in any way?*

A.—Although albuminuria has been observed in animals no ill effects have been reported in man, even though adrenaline has been injected every few hours for years on end. Of course sepsis may occur from neglect of sterile precautions, but it is surprisingly uncommon. In addition there may be shock-like symptoms if the adrenaline is maladroitly injected into a vein. Extremely rarely a sensitization to adrenaline may develop which expresses itself in localized atrophy and scar formation. No harm need therefore be anticipated from an injection of 1/2 c.cm. of 1-1,000 adrenaline every 5 to 6 hours for some days, though it might be wiser and more effective to use 1/4 c.cm. every 2 to 3 hours, the guiding principle in the adrenaline treatment of asthma being "little and often."

Coarse Tremor in the Elderly

Q.—*An elderly lady has recently developed a very coarse tremor of both hands. This makes eating and the performance of simple tasks very difficult. Only the wrists and hands are affected; there is no evidence of Parkinsonism; and her general health, mentally and physically, is good. Hyoscine hydrobrom. gr. 1/200 t.d.s. is without effect; bromide makes no difference. The movements stop during sleep. Is any other treatment likely to benefit?*

A.—The coarse senile tremor described in this question is very resistant to the drugs used in Parkinsonism. Belladonna, stramonium, and hyoscine have their main effect on the rigidity of the muscles, and do not improve the tremor of Parkinsonism. I cannot suggest any medicinal treatment which will help these patients, but one is usually impressed by the skill with which the patients continue their daily lives in spite of the tremor.

Late Walking

Q.—*What are the causes and elucidation of the case of a child aged 2 years who is stated by the mother never to have walked yet? I can find no abnormal physical signs and the child appears intelligent enough for its age.*

A.—Late walking is sometimes a familial failing and in such cases nothing to worry about. But before this optimistic diagnosis is reached two groups must be carefully excluded—those with mechanical causes, and those with mental defect. Under the former come such causes as congenital dislocation of the hip—often difficult to detect without *x*-ray examination if bilateral—rickets, and other causes of muscular hypotonia, including the serious dystrophies. Mental defect of a mild degree is by no means easy to exclude. In the present case the clue lies in the dates at which the child passed earlier milestones—e.g., holding up of head by three months, sitting up by six months. In out-patient experience mental defect is the commonest cause of late walking.

Infections in Pregnancy

Q.—*Is there any evidence for the belief—which I share—that pregnant women are less liable to incur the common infectious fevers (including whooping-cough and mumps) than non-pregnant women? (It is assumed, of course, that they have not previously suffered from the disease in question.) Furthermore, is there any particular danger to the breasts or ovaries of the pregnant woman aged 35 exposed to mumps infection?*

A.—The belief that a pregnant woman is less liable to incur infectious fevers appears to have arisen from observations made in respect of scarlet fever and as a result of confusion between scarlet fever and scarlatinal rashes occurring in association with streptococcal puerperal infections. It was noted that women sometimes developed such rashes and pyrexia a few days after delivery, and, on the assumption that they suffered from scarlet fever, it was argued that, having been immune to the disease during pregnancy, these women became susceptible again after delivery. Braxton Hicks, amongst others, published observations of this kind and reached conclusions to this effect in the latter part of the nineteenth century. Although many of the older writers commented that scarlet fever is rare during pregnancy—and the cases reported are certainly few in number—yet there is no definite evidence to show that pregnancy confers any sort of immunity to scarlet fever and the other infectious diseases. The majority would agree with the following statement which appears in DeLee's *Principles and Practice of Obstetrics* (seventh edition, 1938): "A pregnant woman is not immune to any disease which may affect her in the non-pregnant state, and, contrary to the old notion, she is more susceptible to some." One of my own patients recently contracted whooping-cough during pregnancy.

Mastitis and oophoritis are among the rare complications of mumps at any time, and there is no reason to believe that the breasts or ovaries are in any special danger if mumps is contracted during pregnancy.

Diagnosis of Coronary Thrombosis

Q.—*What are the main clinical points in the diagnosis of coronary thrombosis? What is the differential diagnosis, and what electrocardiographic changes clinch the diagnosis?*

A.—A concise description cannot be of any real practical value; such a common and important disease deserves at least careful study of a full account in a textbook. Myocardial infarction, resulting as a rule from coronary thrombosis, may cause acute substernal pain, of a crushing, burning character, the onset of which is frequently at rest or during sleep. The pain may radiate to either arm or to the neck or to the back; it is not relieved by cessation of activity, nor by nitrites. Its duration may be from hours to days. It is often associated with vomiting. The damage to the myocardium may cause acute failure, shown by severe dyspnoea. There may be grave shock, marked by ashy pallor, fast pulse, low blood pressure, sweating, and a subnormal temperature. Illness, fever, leucocytosis commonly follow the attack. Syncope may occur at the time of onset. Physical signs may be inconspicuous. The mitral first sound may become weak; gallop rhythm may appear; some new enlargement to the left may be detectable. Sudden signs of failure shown by oedema of the bases of the lungs and venous engorgement may be seen. A pericardial rub is sometimes heard later.

In a fairly high proportion of cases the condition is painless: dyspnoea, or vomiting even to acidosis, may dominate the picture. Although coronary occlusion may occur during exertion, persistence of the pain on rest serves to differentiate from angina of effort. Severe substernal pain at rest may be provoked by a rise in pulse rate and blood pressure. But it is controlled by nitrites. A mild case may masquerade as one of severe indigestion, but careful inquiry and the usual sequelae given above should distinguish it. Sometimes the symptoms are so mild that the patient forgets all about it.

Dissecting aneurysm of the aorta causes similar pain. It is rarely survived, and is almost always associated with hypertension. The aneurysm should show in the skiagram later if one can be taken. Gall-bladder colic and a perforation of a peptic ulcer produce upper abdominal pain which may be partly thoracic and cause great rigidity of the abdominal muscles. Vomiting may occur with either, and shock is conspicuous in perforation. Diaphragmatic pleurisy may cause intense epigastric pain and great restriction in breathing, with rigidity of abdominal muscles. Spontaneous pneumothorax causes thoracic pain—usually to one side—dyspnoea, and its own peculiar signs.

The electrocardiographic changes are recognized as two main types, depending on whether the infarct is at the front or the back of the left ventricle. In the early stages of the former there is positive deviation of the RST phase from the isoelectric line. This is soon followed by T1 negativity, which is often marked by the typical Q1 T1 pattern. In Lead 3 the converse is seen. 4R, and better 4F, show a negative T wave, and may be diagnostic when the limb leads are doubtful. In posterior infarction there is positive RST deviation in Lead 3, often followed by a negative Q3 T3 pattern. Lead 1 shows the converse. Lead 2 tends to follow Lead 3, and the precordial leads are rarely affected, except for enhanced T voltage. In some cases these changes give place to normal appearances; in others they remain as long as the patient lives, or until another infarction alters them.

? Fröhlich's Syndrome

Q.—*A man aged 22 years had an operation ten years ago for non-descended testis. Both testes are down in his scrotum now, but of a small size—cherry-stone. He weighs 10 st. 12 lb., and his fat is of feminine distribution. There is no axillary hair, but a few hairs over the pubis have developed since the administration of 10 mg. testosterone propionate twice-weekly. No libido. What is the prognosis?*

A.—The diagnosis may be Fröhlich's syndrome, in which case the small infantile testes are due to a deficiency of pituitary gonadotrophic hormone; or the condition may be eunuchoidism; there being a primary hypogonadism. In both cases testosterone would produce secondary sexual characteristics—e.g., pubic and facial hair, enlargement of the penis, libido with erections, and potency. The dosage, however, should be greater than that used—e.g., 25 mg. injected three times weekly. Alternatively, 5 mg. of methyl testosterone sublingually three times a day; or the implantation of 600 or 800 mg. of testosterone propionate subcutaneously. These forms of therapy, however, would not induce development of the testes; nor would they render a patient fertile as distinct from potent. In eunuchoidism gonadotrophic hormone is of no avail; but in Fröhlich's syndrome, or in any case where the primary lesion is a pituitary deficiency, gonadotrophic hormone, 500 units twice weekly for six weeks, may cause development of the testes and associated secondary sexual characteristics. The therapy would probably have to be repeated intermittently to maintain this condition, and a combination of this therapy, together with testosterone, is advisable.

Attempts to develop the germinal epithelium and spermatogenesis by gonadotrophic hormone of pregnant mares' serum, or of the pituitary gland, are not likely to be successful in the majority of cases, but could be tried.

About Sulphonamides

Q.—*The M.R.C. War Memorandum No. 10 on the medical use of sulphonamides states that "solutions of the sodium salts of sulphonamides must never be injected intrathecally." A modern textbook, referring to cerebrospinal fever, states: "The intrathecal route is no longer used for therapy; intrathecal serotherapy is ineffective; intrathecal sulphonamide therapy is dangerous, and must never be considered." (a) What damage is likely to occur if sulphonamides or their sodium salts are injected intrathecally? (b) Is it permissible to administer in this way sulphonamides or their sodium salts under exceptional circumstances? (c) Is the dosage recommended in the M.R.C. Memorandum now out of date, and may considerably larger doses be properly given with safety? If so, by how much may they be increased?*

A.—The highly soluble sodium salts of the sulphonamides are strongly alkaline, and will cause necrosis if injected into any tissue: they are therefore suitable only for intravenous administration. In the early days of the sulphonamide treatment of meningitis a 0.8% solution of sulphanilamide was injected intrathecally: contrary to the statement quoted, this proceeding is safe if properly carried out. The other sulphonamides are relatively so insoluble that little is to be gained in this way; but Somers (*Lancet*, 1939, **1**, 921) described the successful treatment of Sudanese natives with cerebrospinal fever under most primitive conditions by injecting a *suspension* of sulphapyridine intrathecally. The method has been given up because it is now well known that an adequate concentration of the drug is rapidly produced in the cerebrospinal fluid by oral or other simple methods of administration.

We know of no reasons for supposing that the dosage recommended in M.R.C. War Memorandum No. 10 is inadequate. The only authoritative statement conflicting in any way with its recommendations is a recent report of the Department of Health for Scotland on the treatment of cerebrospinal fever, and the point of difference is the superiority of sulphanilamide over the other drugs in the extensive Scottish experience quoted. The effect of the scale of dosage seemed to vary at different age periods, and by no means pointed to any necessity for a general and considerable increase. These facts were mentioned in a full review of this report in the *Journal* of Oct. 7, 1944 (p. 475).

It is not clear whether the question refers only to cerebrospinal fever or embraces the treatment of other forms of purulent meningitis. The proper treatment of streptococcal, pneumococcal, and staphylococcal meningitis, especially if resistant to sulphonamides, is by the intrathecal injection of a solution of penicillin, reinforced if necessary by intramuscular administration.

Progesterone for Sterility and Abortion

Q.—*What is the technique of giving corpus luteum hormone, and dosage, in cases of sterility and habitual abortion?*

A.—The problem of sterility is extremely complex, and in many cases no cause can be found. It has been shown that in some cases, even when the menstrual periods are apparently regular and normal, ovulation does not occur and a secretory endometrium is never formed. It is difficult to imagine, however, how the administration of corpus luteum hormone could help such cases, which are due to failure of ovulation. It may be that other cases of sterility are caused by a deficiency of the corpus luteum, and thus the endometrium is improperly prepared for the reception of the fertilized ovum. Such cases may benefit from the administration of corpus luteum hormone in the second half of the menstrual cycle. Three to five units (3 to 5 mg.) should be given twice weekly in the fortnight before menstruation is expected.

Habitual abortion is also a condition which may arise from a variety of causes. Some authorities believe that in many cases abortion takes place because of deficiency in the secretion of corpus luteum hormone. In such cases progesterone may be given. The usual dose is 5 units (5 mg.) twice or thrice weekly until the 16th week of pregnancy. Larger doses—10 or even 20 mg.—are recomnended by some authors, and others state that treatment should be continued until the 34th week of pregnancy.

The doses given refer to progesterone administered by injection. There is a preparation—pregneninolone (ethisterone)—which has the action of progesterone when given by mouth; but when this is used he dose is five to six times the amount required when progesterone s given intramuscularly.

Pityriasis Rubra

Q.—*What is the correct treatment and prognosis of a case of pityriasis rubra in a man of 60 following a course of myocrisin 1.2 g. in all)? The condition has been present for six months and arge areas are clear, but the scaling persists on the face, the legs, and in the flexures. He has had intravenous thiosulphate, autohaemotherapy, and other treatment.*

A.—If, as seems from the question, the eruption is clearing or has cleared from many areas, recovery is possible. Treatment should be of the simplest kind, such as boric-vaseline or other non-irritating applications. The general condition of the patient requires constant attention, including a search for focal infection. In some cases vitamin B_2 complex has appeared to help. Occupational therapy is desirable to counteract the introspective habit.

Cerebral Thrombosis

Q.—*A woman aged 70 had about three weeks ago an attack of what must have been a slight cerebral thrombosis. She did not lose consciousness or muscular power in the limbs. Present symptom is aphemia and some diminution of visual acuity, due, presumably, to central causes, as no improvement in regard to small types can be obtained by increasing presbyopic correction. She has always been active and healthy. B.P. is 170. Urine normal. What is the prognosis in respect of the speech defect at her age? Is she at all likely to recover?*

A.—On the description one would agree with the diagnosis of cerebral thrombosis. At the age of 70 the prognosis in the speech defect is unfavourable and recovery unlikely, although ability to say solated words such as "yes" and "no" may return. On the other hand, further thromboses are likely to occur at a later date. The diminution in visual perception may be associated with a similar vascular lesion or reduced vascularity at or near the occipital pole—he centre for macular vision.

Action of Ethylene Diamine

Q.—*What is the action of the ethylene diamine in cardophylin? Has this preparation really any effect on the respiratory centre, and does it actually possess its reputed action in Cheyne-Stokes espiration?*

A.—Cardophylin, also known as aminophylline or euphyllin, is a ombination of theophylline with ethylene diamine. The action of the ethylene diamine is to enhance the effect of the theophylline. Van Heerswynghels[1] showed that, in anaesthetized dogs, the stimulation of respiration produced by an intravenous injection of the ompound was greater than the summation of the two drugs given simultaneously. A similar finding was described by Young and Gilbert[2] on the rabbit's bronchiole, when theophylline-ethylenediamine had a protective action against histamine, but no comparable effect was shown by either drug given alone. The compound s believed to exert a direct chemical stimulation on the respiratory entre, although some workers attribute its effect to an increase in erebral circulation. Marais and McMichael,[3] however, argue that, f it were a vascular effect, a vasodilatation of the cerebral vessels would cause diminished ventilation in normal subjects; this is not the ase. Theophylline with ethylene diamine restores normal respiratory rhythm in Cheyne-Stokes respiration in animals and in man. Ethylene diamine, in man, produces an intense hyperpnoea, while theophylline has only a temporary effect. Their combination causes more prolonged abolition of periodic breathing, sometimes for a umber of hours.

"Pyknolepsy"

Q.—*A girl now aged 6 years began to develop at the age of 3½ ears attacks diagnosed as "petit mal." Phemitone and phenoarbitone were of no avail. The child is well developed mentally and physically; there is no family history of epilepsy. What is the rognosis and what treatment is recommended? If the "fits" do ot markedly diminish in number on treatment with bromides or he barbiturates, am I justified in labelling the condition pyknolepsy nd giving a correspondingly favourable prognosis?*

A.—No, there is no justification in making a diagnosis of pyknolepsy if petit mal in a child does not respond to sedatives. There is no sound evidence at all that pyknolepsy and petit mal are different conditions, and I personally never make the diagnosis of pyknolepsy. In any case, the only distinction advanced to support the existence of two separate diseases is that pyknolepsy invariably has a favourable prognosis; consequently if petit-mal attacks cease they are in retrospect called pyknolepsy. The clinical pattern of the attacks and their electro-encephalographic changes are identical whatever the diagnosis. The case should, therefore, be treated as petit mal, and phenobarbitone, bromides, and even soluble phenytoin tried, alone and in increasing doses, in combination, and with other drugs such as belladonna, until an improvement is obtained.

INCOME TAX

Payments for Dispensing, etc.

"Inquirer" pays £75 a year to his wife for assistance in keeping the books and £52 a year to a part-time dispenser. What is his liability (if any) with regard to the "pay-as-you-earn" procedure?

⁂ An employer is not required to deduct tax from payments not exceeding £2 a week unless he has received a tax-deduction card for that employee from the income-tax office. If, however, he pays more than £1 a week to a *new* employee he should notify particulars of the payment to the inspector of taxes. The payment of £75 a year to his wife will not affect "Inquirer's" title to the full £140 "married" personal allowance.

Pension to Caretaker

F. W. inquires whether a pension paid to the former caretaker of his surgery of £1 per week is allowable as an expense of carrying on his practice.

⁂ Yes, such payments are allowable.

Liability as Assistant

H. D. is employed as an outdoor assistant at a salary of £650 plus free board and lodging. His professional expenses, including wear and tear of car, amount to £52, and he pays £16 per annum in life insurance premiums.

⁂ On these facts the amount of tax payable for the year is roughly £190, leaving a net monthly figure of, say, £38 payable by his principal. The reason for the sharp increase in tax over the previous year's figure is that the additional remuneration he is now receiving carries the full 10s. rate liability.

Casual Earnings of Married Woman

H. M. has, during the past two years, done a certain amount of work for local practitioners. Does she come within the "pay-as-you-earn" system?

⁂ In our opinion—no. H. M. should claim to have her earnings assessed under Schedule D, and we think that that claim will be admitted. As, however, she is entitled to the 1/10th deduction for earned income and the special allowance of £80 given in respect of a married woman's earnings, no actual liability to tax seems to have arisen so far. It may be advisable for H. M. to explain her circumstances to the local inspector of taxes, so that if the occasion arises she can refer a future employer to the inspector's office for confirmation that tax need not be deducted under "pay as you earn."

Depreciation of Car

R. S. inquires as to the basis on which depreciation should be calculated.

⁂ The basis is the "written down" cost of the car. For example, suppose that the car cost £300 in 1940 and a claim is to be made for the financial year 1943–4, the amount will be ascertained as follows:

Cost in 1940	£300
Allowance 1941-2	60
	£240
„ 1942-3	48
	£192
„ 1943-4	38

The allowances as shown above are increased by 1/5th; thus the actual allowance for 1943–4 will be £38+£8=£46.

S. C. bought a car in 1938 for £235, second-hand. Allowances have been made for income tax amounting in the aggregate to about £200, leaving the written-down cost at £35. S. C. is advised that the market value of the car is, say, £550. Is any adjustment of the basis of the allowance due in future?

⁂ No. The basic intention of the depreciation allowance is to give a deduction for the *cost* to the user, spread reasonably over the working life of the car or other "machinery"; it is expressly provided that the aggregate amount of the deductions shall not exceed the actual cost to the person who has had the benefit of the deductions.

LETTERS, NOTES, ETC.

Oxalated Blood for Cell Counts

Dr. MARTIN FOLAN (University College, Cork) writes: In "Any Questions?" of Dec. 2 (p. 744) you reply to an inquiry regarding the use of oxalated blood for cell counts. Admittedly, the use of an empirical amount of oxalate or citrate will lead to many inaccuracies, due to shrinkage of the cells. In the clinical laboratory here we serve a wide provincial field, and for blood counts issue tubes containing the balanced potassium and ammonium oxalate mixture of Wintrobe. (See Whitby and Britton's *Disorders of the Blood*, 1942.) These are designed for 5 c.cm. of blood, *accurately* added, and the whole well mixed by gentle inversion, as frothing results in uneven cell dispersions. Films are provided by the physician in charge of the case, as even this oxalate mixture does not give good cellular morphology in films prepared from it. In my experience this method has given results that agree closely with those prepared at the bedside, and provides a convenient solution to the necessary, though undesirable, practice of sending blood through the post for cell counts. If not more than 12 hours old the specimen may be used for fragility tests provided that the blood is well aerated, as no correction is required for shrinkage.

Rocking Movements in Sleep

Dr. SUSANNA M. HALLIDAY (Cornwall) writes: Rhythmic movements are stated to be normal in a child under 3 in the state between waking and sleeping. Does the writer know whether these movements were common thirty years ago, before it became fashionable systematically to neglect babies? Does he know of a single case occurring in a baby whose mother troubles to go to him when he cries or shows other signs of distress? Is the child who does not show these movements abnormal?

Translation, Please

Dr. MAURICE MCELLIGOTT writes: I should be grateful if any of your linguistic readers would solve the following conundrum. Fifty years ago in Ireland what we call "carbuncle" was quite commonly termed "anthrax" by educated laity. "He has an anthrax on the back of his neck" was a usual expression when speaking of a sufferer from carbuncle. To-day in France the equivalent of our word "anthrax" is *charbon*, and of our "carbuncle," *anthrax*. A recent German medical lexicographer translates *Lumpensammlerskrankheit; Milzbrand, Pestbeule* into the Spanish *carbón*, which seems correct enough. However, he gives for the Spanish *carbunco* the alternative of *Milzbrand* and *Karbunkel*. Hence I would ask a medical linguist better instructed than myself to enlighten me as to the correct Spanish, French, and German terms for the diseases due to *Bacillus anthracis* only.

Hyoscine for Sea-sickness

Capt. J. C. GILBERT, R.A.M.C., writes: Having acted as M.O. on small troopships for the past two years, and in the course of such duties having covered 35,000 miles in Northern waters, waters which, even in summer, are none too kind to the squeamish "tummy," I may perhaps be allowed to record my views on the use of hyoscine both prophylactically and for curative purposes. Hyoscine hyd. gr. 1/100 administered half an hour before sailing, followed by a second dose in four hours and thereafter every six hours, will in 80% of cases prevent sickness and enable meals to be taken. For voyages of over three days' duration the dose can gradually be reduced as the land-lubber gains his sea-legs. For an 8-hour night journey where sleep is permitted one nembutal or hyoscine hyd. gr. 1/100 and phenobarbitone gr. 1½ is ideal. I have seen no harmful effects from hyoscine. A few men have complained of slight dryness of the throat and of slight drowsiness (which complaint I have never heard from a man on duty). In cases where the patient is already sick and has had no treatment gr. 1/75 subcutaneously works wonders, and the dosage can be continued orally; but the really genuine severe cases of travel sickness respond best to hyoscine gr. 1/100 and morphine gr. 1/8 subcutaneously.

Rectal Examination during Labour

Dr. H. A. MURRAY (Exeter) writes: I was interested to read Dr. Bradlow's description of a case of locked twins (Oct. 21, p. 582), primarily because I have always thought rectal examination during labour to be an unsurgical procedure. Despite the lead given by the "mighty" I have never practised this method, and never will. Vaginal examination is much less unpleasant and embarrassing for the patient, and more certain diagnostically. Had Dr. Bradlow done a P.V. sooner he would have diagnosed the condition earlier and saved the patient much suffering. Surgeons always do "clean" cases first and septic ones last, but the obstetrician who examines rectally is deliberately making himself and the field of operation septic. It would be more surgical to plug the anus, and hope it would remain so until after delivery.

Regional Ileitis

Mr. JAMES MORONEY, F.R.C.S. (Liverpool) writes: In reply to a question on this subject in your issue of Dec. 9 (p. 778) you state "The ideal treatment is primary resection. . . ." The vast majority require no operative treatment at all. If obstruction is present the safer and simpler procedure of entero-anastomosis performed through healthy bowel wall is very satisfactory. While I agree tha resection may be necessary on occasion, I feel that it is far from "ideal treatment" for the majority.

Headache and "Acute Abdomen"

Dr. T. L. CRAWHALL (Watlington, Oxford) writes: Ever since you published a note on migraine being mistaken for appendicitis, have wanted to send in this aphorism, which I think is original "An 'acute abdomen' with a headache is never an acute abdomen!" I do so now because the headache in early pneumonia should distinguish it from an acute abdomen in spite of abdomina pain and rigidity.

Injuries to the Supra-orbital Nerve

Major H. J. STERN, R.A.M.C., writes: The following notes on injuries to the supra-orbital nerve may be of interest. Although the clinical picture has been observed before, not everybody seems to be aware of its existence, so that diagnosis and treatment are frequently delayed. Here is a short description of a typical case: A man had knocked the right side of his forehead against the door of a tank when leaving it. He did not take much notice of this, but after a few hours he started to complain of headaches which became so violent that he had to report sick. He was evacuated and admitted to hospital two days later, still suffering from very bad headaches. An *x*-ray of his skull failed to show any bony injury. The possibility of a concussion or a subdural haemorrhage was taken into consideration, but neither these nor other attempted diagnoses were satisfactory. As the patient began to complain of watering of his right eye he was referred to the eye specialist on the fourth day after the injury. He was still complaining of violent headaches on the right side, and there was clearly a hypersecretion of tears in his right eye. There was no disturbance of the eye movements or the pupillary reaction, and the fundi were normal A very slight but extremely tender swelling in the right eyebrow region was seen, just over the supra-orbital notch. The patient explained that the headaches were "outside" and that he had a peculiar "raw" feeling all over the right side of his scalp. This description and the tenderness over the supra-orbital nerve made the diagnosis of traumatic neuritis of this nerve clear. The cold compresses on his forehead which had made his discomfort, if anything, worse, were discontinued, and local application of heat and antineuralgic drugs served to clear up the condition rapidly. The supra-orbital nerve is a branch of the first division (ophthalmic nerve) of the 5th cranial nerve. Another branch is the lacrimal nerve, which supplies the lacrimal gland. This explains the frequen association of watering of the eyes with injuries to the supra-orbita nerve; it is caused by a reflex irritation of the fibres of the lacrimal nerve by the sensory fibres of the supra-orbital nerve. It is interesting to note that in one of the observed cases a symptomatic herpes zoster of the area of distribution of the supra-orbital nerve appeared on the sixth day after the injury. This eruption has to be regarded as due to a secondary involvement of the sensory nerve, not as a result of an infection with herpes virus.

Cracked Fingers

Dr. H. VICKERS (Uxbridge) writes: As a past sufferer from cracked fingers I have read with interest the suggestions put forward in the *Journal* during the last few weeks. I have tried, I think, all the remedies suggested, but there is one remedy which I now use and which keeps my hands in good condition. Incidentally I do a lo of gardening and hard work with my hands, and have tried the remedy with complete success during the past five years, even during the severe winter the first year of the war. After washing I rub my hands, nail edges, and the tips of my fingers regularly night and morning, and as often as possible during the day, with a mixture of equal parts of glycerin and lotio rubra; nothing else. A very small quantity is required, but it must be rubbed in carefully. I is much pleasanter than having to wait till a crack appears and then use plasters and other unsightly remedies. The fingers and quicks keep hard and dry and are easily kept under control. I can thoroughly recommend this as effective, and, further, if through any unforeseen cause a crack should appear, the application, if regularly applied to the crack, promotes a very speedy and not unsightl remedy.

Correction

In the annotation, "Arsenic in the Treatment of Malaria, published in the *Journal* of Jan. 6 (p. 19), the dose of mapharse (known in this country as mapharside) was by mistake given a 0.4 to 0.6 g. It should have been 0.04 to 0.06 g.

AERIAL INFECTION*

BY

MAURICE MITMAN, M.D., M.R.C.P., D.P.H.

Medical Superintendent, L.C.C. River Hospitals, Joyce Green

For many years it was widely held that smallpox could be conveyed for a mile or more by aerial convection, and there are still some who hold this view. It is now believed that alleged instances of long-distance transmission do not bear critical examination: some fault in isolation technique allows the disease to be conveyed by undetected vectors. But aerial convection should not be dismissed too lightly, for phytopathology provides abundant evidence of long-distance dissemination of plant pathogens.

Extramural Aerobiology

The atmosphere contains vast numbers of living and dead particles derived from, and dependent upon the nature of, the soil, its flora and fauna. Many seeds and pollens are specially adapted for aerial transmission; smaller living particles such as fungi, spores, bacteria, and viruses need no such adaptation to remain suspended. The number remaining air-borne depends on such meteorological factors as the vertical and horizontal movements of the air, and upon precipitation, which in turn is governed by size, shape, and density of the particles. Viability depends on the nature of the particle, its ability to survive desiccation, extremes of temperature, and the lethal effect of radiation; in this connexion the protection provided by the non-living particle on which organisms are often carried is of some importance. This state of suspension of particles and their rate of settling are worth closer examination.

Because of the resistance of the air, particles do not fall with increasing velocity, but reach a constant velocity when a balance is struck between accelerating and resisting forces. Stokes's law expresses the constant velocity of descent of a small suspended sphere in terms of its radius and density, and the density and viscosity of the fluid medium through which it is falling. In perfectly still air the rate of fall of, say, a staphylococcus 1 micron in diameter (i.e., 1/1000 mm.) would be about 1 cm. in 5 minutes; and of a small-sized droplet of mucus 50 μ in diameter about 18 in. a minute. In the presence of a steady wind with a velocity of 10 miles an hour the staphylococcus would be carried for a distance of over 900 miles before reaching the earth from a height of 10 metres; the 50 μ droplet would be carried for a third of a mile. If there were a rising current of air with a velocity in excess of the fall the particles would be carried up—the smallest to great heights. The air for a mile up contains vast numbers of bacteria and spores; above two miles the number decreases rapidly, but Armstrong (1936) found them in the stratosphere 70,000 ft. up. Over large masses of water the number of terrigenous organisms decreases rapidly, but specimens have been collected 130 miles out to sea; on the other hand, viable marine organisms have been collected 50 miles inland. Organisms are present in rain and have been found in falling snow in Antarctica—far from their place of origin. There is an aerial cleansing action in precipitation which is worth remembering. Climatic factors, then, govern the transport of aerial organisms; indeed, meteorological investigations are of the utmost importance in the epidemiology of some plant diseases. Wind plays a great part: the spores of wheat-stem rust, a destructive fungous disease, have been carried in large numbers for such enormous distances as 1,000 miles in such a short time as 48 hours, to give rise to outbreaks of rust a week or 10 days later (Stakman, 1942). Jacob (1940) maintained that the horizontal distance over which micro-organisms can be transported is almost limitless, although their effective range is determined by their ability to survive. Terrigenous organisms of the air are remarkably resistant. They survive exposure to direct sunlight, heat, and dryness for days or weeks, although, paradoxically, they die rapidly on exposure to sunlight after isolation in the laboratory. The effect of humidity on survival is disputed: Wells (1936) found ultra-violet radiation to be 10 to 20 times more germicidal in dry air than in humid air, but Renschler (1940) decided that relative humidity does not increase the resistance of air-borne bacteria. There is, then, no reason why human pathogens should not be carried over considerable distances; but as they have never been recovered from the upper air or marine air, the inference is that they do not long survive exposure. Compare the absence of pathogenic bacteria over the sea with pollen grains, which may be found hundreds of miles from land in numbers in inverse ratio to the distance from the source.

Intramural Infections

This brings me to the first important point I want to stress, which is that, in my opinion, most human respiratory infections take place indoors. Such diseases are still the greatest cause of morbidity and mortality, and if we can be sure that they are always intramural events we can direct our energies for their control along narrower channels.

That pestilential air was a vehicle of contagion and infection was believed hundreds of years before the germ theory of disease was propounded. Perhaps the most surprising period was the first 35 or 40 years of this century, during which time the theory of air-borne diseases was practically abandoned. It started with Flügge's (1897, 1899) description of infectious droplets. They explained so many problems of contact infection that they came to be accepted as the mode of transmission of most respiratory infections. Since droplets rapidly fall to the ground within a few feet of their source it was assumed that the infector and the infectee had always to be in close proximity. Certainly for most of my professional life fever practice was based on the hypothesis that practically all cross-infections were attributable to hands or droplets, although the behaviour of chickenpox seemed to contradict this from time to time; smallpox, of course, was in a class by itself. Not until Wells and Wells's (1936) exposition of droplet nuclei did "aerial infection" reappear.

Now that the term is reintroduced we must be clear what we mean by it. Long-distance aerial transmission is of course excluded, but there has been a tendency to exclude droplet infection also, limiting the term "air-borne infections" to those occurring more than 4 ft. from the source (Cruickshank, 1940). Our terminology of the modes of infection is confused and requires clarification. The average examinee states that direct contact is the commonest mode of spread of infectious diseases, but has a very hazy conception of what the term means; when pressed it usually transpires that close proximity to the patient in time and space is meant, not contact in the sense of touching. I should like "contact" restricted to "touching," but I doubt if it could be displaced from its use as a noun to indicate a person exposed to infection. "Aerial infection" should embrace all those modes of transmission in which the path of the infective agent lies through the air—those which pass through a circle in Fig. 1. Droplets, their nuclei, dust, and direct discharges may pollute the air. In the case of droplets the infection is transmitted immediately to the infectee; with the others there is not necessarily this proximity in time and space. "Direct infection" or, if you prefer to retain the term, "direct contact" could then be used for transmissions which occur when infector and infectee touch, as in kissing, copulation, contact with discharges or the infected hands of an attendant. "Indirect infection" by mediate means implies the contamination of inanimate objects such as fomites and food (those in rectangles in the diagram) and their conveyance, sometimes at a much later date, to the infectee, who may be a considerable distance away.

Droplets Expelled by Sneezing

To me, one of the most surprising disclosures was the extent to which sneezing adds to the bacterial load of a room. Compared with the gentle bacterial showers which coughing, talking, and laughing bring, sneezing contributes veritable intramural storms. Another unexpected revelation was the origin of the droplets expelled during sneezing: photography makes it clear that they are almost all derived from the mouth, and few or none from the nose. After a sudden inspiration, often with extension of the head, the forcible expiration begins with a quick flexion of the head, a narrowing of the mouth, and the expiration of air at high speed over the secretions of the mouth and pharynx, which are atomized and forced out through the narrowed orifice at a maximum jet velocity of 46 metres or 152 ft. per sec. The duration of the sneeze is about 1/10 of a second. The atomization is more efficient—i.e., the droplets become smaller—as the velocity of the air-stream increases and the size of the orifice decreases; among other factors influencing size of droplets are surface tension, viscosity, particulate inclusions, and evaporation. Droplets vary from 7 μ to 1,000 μ or more, but commonly two-thirds of them are smaller than 100 μ (i.e., 1/10 mm.). This is an important figure, because Wells (1934) considers 100 μ to 200 μ as the dividing-line between droplets likely to fall and those likely to remain suspended.

Bourdillon and Lidwell (1941) estimated the number expelled by a vigorous sneeze at 100,000, but Jennison (1942) gives an average figure of 20,000, with a low limit of 4,600 for a weak, stifled sneeze. These figures are enormously higher than those for coughing and talking. In coughing, the droplets are produced chiefly in the pharynx, and only a few dozen or a few hundred escape because the mouth is kept open. Flügge (1921) also distinguished bronchial droplets expelled during coughing from oral ones. In talking, the number of droplets expelled depends on the consonant enunciated: explosives such as "p" and "t" cause a few hundred, and vowels practically none. Theoretically, a particle 1,000 μ (or 1 mm.) in diameter, ejected from the mouth with a velocity of 152 ft. per sec., will reach the floor 15 ft. away; the smaller the particle the less its kinetic energy and the shorter the distance it will go. Using the technique of flash photography, Jennison (1941) showed that few of the particles from a sneeze fell more than 2 or 3 ft. away. Many remained air-borne. The smaller the droplet the more easily was it suspended. In this connexion it is of great importance to appreciate that droplets become much smaller after expulsion. Within a quarter of a second a droplet of water 150 μ in diameter is completely evaporated in still air (Jennison, 1942). As most sneezed droplets are smaller than this it follows that within a fraction of a second most of them have evaporated to sizes which permit them to remain suspended as droplet nuclei.

I have not been able to find a definite statement as to the size of a droplet nucleus, but I would infer it to be less than 5 μ, each particle consisting of individual bacteria or minute masses of organisms or viruses on a small quantity of the vehicle. Bacteria in the air act as condensation nuclei, and the vehicle is usually a film of water, the thickness of which depends on the humidity of the air (ZoBell, 1942). Wright (1940) says the whole nucleus is very little larger than the included bacteria or other particles. To support a droplet 10 μ in diameter an air current with an upward velocity of less than 1 ft. per minute is required. As the average movement in a naturally ventilated room is about 25 ft. per minute adequate lifting force is available for most small droplets, which are readily dispersed throughout the room by convection currents. The deposition of suspended particles on to the floor takes place not at a constant rate but at a geometrically decreasing one: about 16% of air-borne bacteria are still suspended 8 hours after their introduction (Phelps, 1942).

Another point of great interest is the site in the respiratory tract on which inhaled particles are deposited. Hatch (1942) maintains that infection cannot gain entrance to the deepest part of the tract unless the particles carrying the organism are below a certain minimum size. The larger ones are caught in the nose and upper respiratory tract and are removed by ciliary action; a number of the smaller ones manage to reach the alveoli of the lungs. While droplets can infect the upper respiratory tract, only droplet nuclei, he maintains, can cause pulmonary infection. Dust clouds raised by sweeping have a rapid settling rate, and probably few such particles reach the alveoli. By contrast, the average diameter of dust particles normally suspended (as distinct from those raised) is smaller than a bacterium, and Hatch (1942) thinks the idea of bacteria being attached to such particles is erroneous. It is also important to maintain a proper perspective of the degree of contamination of droplets and dust. Although the total number of organisms of all types is comparable with the number of droplets, specific pathogens are relatively few. As for dust particles, their number is enormously in excess of the number of bacteria. Yaglou and Wilson (1942) counted 1,000,000 dust particles per cu. ft. of air as compared with two bacteria

Counts in the open have shown one micro-organism per 100 or more dust particles.

Interchange of Respiratory Flora

In contrast to extramural purity there is abundant evidence of pollution of intramural air by the nasopharyngeal organisms of human occupants (*vide* Harries and Mitman, 1944). The greater the number of occupants the higher the bacterial counts. It has long been recognized that overcrowding promotes infection, but it is not so well known that a fourfold increase in ventilation will reduce the count of an overcrowded room by only 21%, whereas if the occupants are few in number the same air exchange will reduce the count by 65% (Yaglou and Wilson, 1942).

I have for long regarded overcrowded public transport vehicles as the most fruitful venue for the interchange of respiratory flora. The Government's slogan should have been "Is your *dangerous* journey really necessary?" for the flying droplet is much more lethal than the flying bomb. In a recent Scottish White Paper on the distribution of new houses it was stated that failure to link housing with industry had been the most serious error in general housing distribution policy in the inter-war years. I agree, and when houses of the future are sited near places of work there will be eliminated those expensive, exhausting, time-consuming, and health-destroying journeys which take place in overcrowded transport vehicles. A cinema I regard as much safer; overcrowding is forbidden, not for hygienic reasons but because of fire risk—a rare contingency, but one for which expensive allowance is made, since a single conflagration is so much more apparent than a thousand inflammations. I propose to say little on the other factors which add to the bacterial load of a room. The general cleanliness of a room, the degree and nature of the occupants' activities, and the amount of respiratory infection interest us particularly, for they are responsible for the heavy bacterial load of hospital air.

I would like to say a few words about controlling the rate of additions of organisms to a room. The public have responded well to the Ministry of Health's propaganda for respiratory hygiene. The use of the pocket-handkerchief during coughing and sneezing is more widespread than it has ever been. It is impossible to measure the effect of this one change when so many others are taking place simultaneously, but I believe it has materially influenced the incidence of respiratory disease. I might add that I am not particularly fond of the washable pocket-handkerchief, but I do not see a satisfactory substitute yet. Nor do I like the hospital blanket, and I look forward to the day when blankets are no longer made. Despite the reports of the success of oiling bedclothes and floors, I am not greatly impressed by those results with which I am personally familiar, and the method is not free from drawbacks, because some oils used are dermatitic. So long as this possibility remains I am sure the method will not be widely used. Covers for blankets are a compromise of which I have no experience. I was glad, however, to read an account by Chapple (1942) of an infants' ward with a special air-conditioned annexe for premature infants. In the incubator the infant was allowed to lie naked and uncovered: not only had the blankets gone, but so had all the other bedclothes and the bed linen too. This is an advance. I have always wanted to try it on sick people, but it requires an elaborate air-conditioning system and makes nursing uncomfortable.

Air-conditioning does not ensure the degree of disinfection of the atmosphere which might be expected. Increase in the number of air changes will not necessarily reduce the bacterial count; if air is re-circulated, as it often is to conserve heat, it may even increase it. Both washing and filtration of incoming air will substantially reduce the bacterial count of an empty room, but *not*, be it noted, of an occupied one; and the more occupants the greater the pollution. If the spray water used for washing the air is re-circulated the bacterial load may actually increase; for this reason disinfectants are occasionally used for washing. Ultra-violet radiation in the mixing chambers or in the ducts of air-conditioning plants has also been used, but it has drawbacks, such as absorption of the radiation by the walls and interference with the efficiency of the lamps by dust.

Masks I cannot dwell upon: the subject is too big and was discussed recently by Bourdillon. I favour the more extensive use of masks, but am satisfied that an efficient and comfortable one has not yet been devised.

Germicidal Radiation

The oldest method of eliminating intramural infection of the air is by ordinary ventilation. Wells (1936) laid down standards of what he calls sanitary ventilation and maintains that good ventilation cannot be obtained by ordinary methods because the number of turnovers required (100–500 per hour, according to him) is impossible by ordinary or mechanical means. He therefore introduced irradiation of the upper air with ultra-violet light with the object of destroying as many bacteria as would be removed by good sanitary ventilation. McKhann *et al.* (1938) first tried U.V.R. across a corridor as a barrier to infection between two contiguous rooms. Since then a considerable literature has appeared. The method has been much more extensively used in America than here, where Andrewes (1940) reported adversely upon it because of its ineffectiveness in the presence of dust. Nevertheless, experimental and clinical reports are impressive. Wells (1943) reported a marked fall in the incidence of measles and chickenpox over periods of 3 to 6 years in three schools with irradiated classrooms. In infants' homes Barenberg *et al.* (1942) and Rosenstern (1942) obtained considerable reductions in respiratory cross-infections, as did del Mundo and McKhann (1941) in an infants' hospital. Hart (1942) investigated the importance of air-borne pathogenic bacteria in the operating theatre. The most rigid, aseptic surgical technique failed to prevent contamination of some of the clean wounds. With ultra-violet irradiation he was able to secure a considerable reduction in the percentage of such infections and no deaths from wound sepsis over a period of 5½ years. He considered it the simplest and most effective method of eliminating such infections and one which could be used without evident danger to the patient or the properly protected personnel.

There is, of course, no essential difference in the management of aerial infection in operating theatres, surgical wards, or fever hospitals. The practice has appeared in this war of applying fever principles to surgical wards. It was long known from experience that it was undesirable to nurse clean and dirty surgery in the same ward. Now it is known that not only hands but air must be considered. In a busy surgical ward it is almost impossible to suspend all other activities while dressings are being changed, and in my own hospital I have been considering using a separation ward solely for dressings with the object of minimizing aerial infection. I have little doubt that a good deal of the success of the coagulation and Bunyan-bag methods of the treatment of burns and the closed-plaster treatment of wounds is due to exclusion of aerial infection.

Let me return to germicidal radiation and remind you of the position of ultra-violet rays in the electromagnetic spectrum.

Starting with the longest wave-lengths there are first wireless waves whose length is expressed in metres or centimetres; then infra-red rays and visible light measured in microns or thousandths of a millimetre; these are followed by ultra-violet, x- and γ-rays whose wave-lengths are expressed in ten-millionths of a millimetre—i.e., in Angström units (A.U.). The U.V. light band includes wave-lengths from 4,800 A.U. to 2,000 A.U., and the longer waves have different properties from the shorter ones—e.g., maximum pigmentation is produced at 3,850 A.U., whereas maximum germicidal action is obtained at 2,650 A.U. To obtain radiation of these different wave-lengths, different U.V. lamps are required. For germicidal effect a low-voltage, low-vapour-pressure, "cold" mercury-vapour-arc lamp is required, not the type used for ultra-violet therapy. Its main emission band is at 2,537 A.U., which is close enough to the required 2,650 A.U. to be 70% efficient (see Fig. 2). These lamps are simple, slender tubes, resembling the corresponding lighting tubes, and are as easy to change. To give an example of the rating: a common germicidal lamp has a power of 15 watts, an effective length of the burner of 15 in., an overall length in the holder of 18 in., and a tube diameter of 1 in.; the approximate lamp amperage is 0.3 and voltage 56. The temperature of the special glass for transmitting the radiation does not exceed 120° F. Such a tube gives a radiant flux of 25 $\mu W/cm^2$ at 1 metre and its average life is about 2,500 hours. Irradiation of the upper half of a 4,000 cu. ft. room by one of these lamps is equivalent to 45 air changes per hour in terms of Wells's sanitary ventilation. These lamps, like all-U.V. lamps, deteriorate, and the end of the life of the tube is regarded as having occurred when the output has fallen to 66%. The limitations of U.V.R. must be accepted. U.V. lamps have practically no penetrating power, so that their efficiency is materially lowered in a dusty room. The Council of Physical Therapy of the American Medical Association has accepted such lamps for disinfecting air only in hospitals, nurseries, and operating rooms as an adjunct to other methods of asepsis; for the safety of occupants they have accepted an intensity of 20 μW/cm^2 at 1 metre from the lamp as standard.

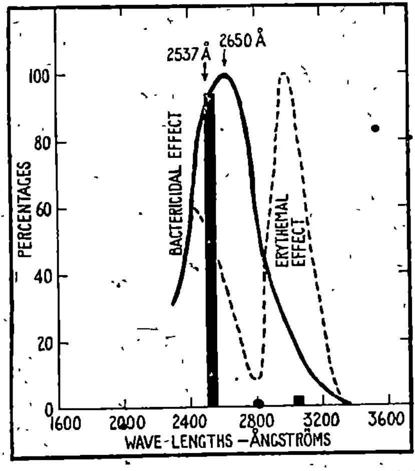

FIG. 2.—Main emission band from a germicidal lamp (2,537 A.U.), shown with the graphs of bactericidal and erythemal effects of ultra-violet radiation. (After Buttolph, 1942.)

U.V.R. for aerial disinfection can be used in three ways. By being directed upwards it produces an irradiated ceiling; natural convection currents carry the organisms upwards, where the air is disinfected by the radiation. The radiation may also be directed downwards to form "curtains" around beds and "barriers" across corridors. Lamps which combine the functions of irradiating the ceiling and producing a barrier are known as direct-indirect types in contrast to the simple indirect type directed upwards. Lamps may also be introduced into air-conditioning plant in the way I have already described.

Dynamics of Crowd Infections

Wells *et al.* (1942) attribute their success in preventing school epidemics to an improvement in the sanitary ventilation, bringing it above a critical level and thereby raising the threshold density of susceptibles. This last term was introduced by McKendrick (1940) into his interesting theory of the dynamics of crowd infections. According to him two factors govern epidemic spread—an actual density of susceptibles and a threshold density (see Fig. 3). When the number of susceptibles is above the threshold an epidemic occurs. As the number of cases rises, the density of susceptibles falls. When it equals the threshold value the epidemic is at its peak. Thereafter, the density of susceptibles having fallen below the threshold, the conditions for epidemic spread no longer obtain and the outbreak exhausts itself when the density is as much below the threshold as it was originally above it. Thus the number of people affected in any outbreak is double the difference between the two densities. It will be clear that an epidemic can exhaust itself long before all the susceptibles are affected, and this agrees with experience. Anything which lowers the density of susceptibles or raises the threshold will either prevent an epidemic or limit its extent. Wells, by improving the sanitary ventilation with U.V.R., diminished the infectivity of the disease and thereby raised its threshold. This conception opens up wide possibilities. If respiratory diseases are indeed intramural events we must, when we rebuild our hospitals after the war, ensure that our architects and engineers incorporate those features which will allow full use to be made of our new knowledge of aerial infection and its control.

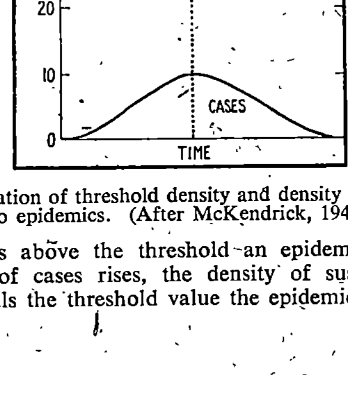

FIG. 3.—Relation of threshold density and density of susceptibles to epidemics. (After McKendrick, 1940.)

Summary

On physical grounds there is no reason why human pathogens should not be carried over great distances and up to considerable heights; but as they have never been recovered from upper air or marine air the inferences are that they do not long survive exposure and that most human respiratory infections take place indoors.

The theory of air-borne infection was practically abandoned for 40 years until Wells described droplet nuclei.

The term "aerial infection" includes all modes of transmission in which the path of the infective agent lies through the air.

Coughing, talking, or laughing contributes gentle bacterial showers to the air, but sneezing causes veritable intramural storms. Of the tens of thousands of droplets expelled from the mouth during a sneeze, about two-thirds remain air-borne. Only droplet nuclei and the finest dust particles are small enough to penetrate to the lungs.

Contamination of air in overcrowded rooms cannot be effectively countered. Overcrowded public transport vehicles are the worst places for the interchange of nasopharyngeal flora; when housing is more closely linked with industry many such journeys will be unnecessary. The Ministry of Health's campaign for respiratory hygiene has already influenced the amount of respiratory disease.

Hospital blankets are an abomination and the results of oiling bedclothes and floors are not impressive.

Air-conditioning does not ensure the degree of disinfection of the atmosphere which might be expected. The use of masks should be extended, but a comfortable and efficient mask has not yet been devised. Trials with germicidal ultra-violet radiation for air purification in children's homes, nurseries, hospital wards, and operating theatres are impressive. The chief limitations of this radiation are its poor penetrating power and its ineffectiveness in the presence of dust.

The new knowledge of the control of aerial infection should be incorporated in post-war rebuilding of hospitals.

THE NATURE OF INJECTABLE LIVER EXTRACTS

A DISCUSSION ON STANDARDS OF POTENCY AND PURIFICATION

BY
W. B. EMERY, B.Sc., A.R.I.C.
AND
W. J. HURRAN, B.Sc., A.R.I.C.
(Glaxo Laboratories Ltd., Greenford, Middlesex)

Since Minot discovered the specific effect of liver in the treatment of pernicious anaemia, and various workers subsequently prepared concentrates suitable for injection, the preparation of such concentrates on a commercial scale has been undertaken in many laboratories. Widely differing methods have been used to make these concentrates or "extracts," with the result that apparently similar products differ from one another to a remarkable degree. The terms used by manufacturers to describe these products also lack uniformity. The fundamental cause of these differences is doubtless the lack of any precise measure of anti-anaemic activity. Although many attempts have been made to devise laboratory tests, these have met with no success, and clinical trials on patients with pernicious anaemia in relapse afford at present the only practicable method of assessing activity.

It is fairly common to refer to a liver extract as being either "crude" or "refined." By the term "crude" we understand an extract that has undergone the smallest amount of processing necessary to render it safe for injection. It will therefore normally contain a comparatively large amount of material other than the active principle, and each millilitre will be derived from a comparatively small weight of original liver (2.5–10 g.).

By the term "refined" we understand an extract that has been derived from a "crude" extract through several additional stages of manufacture, which remove a large proportion of the inert material and very often a part of the active principle also. It will normally contain only a small amount of inert material, and each millilitre will be derived from a much larger weight of original liver (50–200 g.). These descriptions may be useful, but they do not express adequately the differences between extracts, and may even lead to the erroneous belief that all the extracts of any one class are similar to each other.

For several years we have devoted attention to the development of two commercial liver extracts. One would be classed as a "refined" and the other as a "crude" extract. Our investigations have also included laboratory preparation of several highly refined fractions. This work has been carried out in collaboration with a number of pathologists, to whom we are indebted for the necessary clinical tests.

Certain aspects of our work may, we hope, help to clarify some of the obscurity surrounding the nature of liver extracts available to clinicians. To assist the discussion of this work we make use of an arbitrarily defined unit of activity, based on the type of clinical test most frequently used in this country.

Present Methods of Expressing Potencies of Injectable Extracts

There is as yet no standard method of expressing the potency of an extract, and statements made by manufacturers usually fall into one or other of the following three main groups: (*a*) A stated volume of the extract is derived from a stated weight of liver. (*b*) A stated volume of the extract given by injection is therapeutically equivalent to a stated weight of liver taken orally. (*c*) A stated volume of the extract produces adequate haemopoietic response.

Claims for the potencies of liver extracts in terms of the amount of liver used to prepare them (group *a*) may be very misleading, because varying losses of active principle may occur during the purification process. Thus a highly "refined" extract may contain less activity than a relatively "crude" preparation derived from the same weight of original liver. Our experience of process losses given below illustrates this.

Comparison of extracts by relating their potency to stated weights of liver taken orally (group *b*) was a useful device when injectable extracts were first coming into use. Then, most doctors' experience in treating pernicious anaemia was in terms of liver diets, and to express such a relation may have seemed important. Now that injection is the customary form of treatment this type of statement has little value, and is, moreover, misleading—first, because process losses may vary from extract to extract, and, secondly, because the relative efficacies of oral and injectable extracts are not known with any accuracy. Thus, for example, Martindale (1941) quotes a statement that liver given by injection is 20 to 40 times as effective as when given orally, while Minot and Strauss (1943) consider that the probable ratio is nearly 60 to 1.

The statement that a specific volume of an extract is capable of producing an adequate response (group *c*) clearly provides a more direct basis for the comparison of different extracts. The meaning of a statement of this nature, however, depends on what is meant by an adequate response, and the criteria adopted are not always clearly defined. Even when this has been done, comparison of different extracts may be difficult because the manufacturer may have deliberately understated the potency of his extract in order to make allowance for small batch-to-batch variations in potency.

Criteria of Satisfactory Response

All the clinical tests carried out in conjunction with our investigations have been on cases of classical pernicious anaemia not treated recently with other liver extracts or with hogs'-stomach preparations. These cases had initial red cell counts of not more than 2½ millions per c.mm. As criteria of a satisfactory response it has been required, first, that the red cells should increase over the first two weeks of treatment at least as rapidly as required by the formulae of Isaacs *et al.* (1938), Riddle (1940), and Dyke and Della Vida (1942); and, secondly, that a reticulocyte response satisfying the criteria of Minot *et al.* (1928) should be obtained.

Very occasionally we have encountered cases in which the red cells have risen satisfactorily but the reticulocyte response has not quite satisfied the criteria of Minot *et al.* (1928). In these cases the absence of a second reticulocyte response after a further injection has been taken to indicate a satisfactory initial response. Use of the term "satisfactory response" in this paper means that these conditions have been fulfilled. Thus, the criteria of Dyke and Della Vida (1942) require the following increase in red cells over the first two weeks of treatment:

Initial Red Cell Count	Increase in Red Cells
1·0 mill. per c.mm.	1·45 mill.—i.e., to 2·45 mill. per c.mm.
1·5 „ „	1·22 „ „ 2·72 „ „
2·0 „ „	1·00 „ „ 3·00 „ „

Preparation and Comparison of "Crude" and "Refined" Extracts

The material used in the preparation of both "crude" and "refined" commercial extracts discussed here is raw finely minced liver which has not been subjected to proteolytic enzyme digestion before extraction. Only the minimum of fractionation procedures necessary to make the product suitable for injection have been employed in the preparation of the "crude" extract, which has consistently given a satisfactory response on a total dose derived from 60 g. of original liver. Responses which just fail to satisfy the defined criteria have been obtained with a dose derived from 40 g. of original liver.

The original "refined" extract was prepared according to the method of Laland and Klem (1936), involving adsorption of the active principle on charcoal and its removal from the adsorbate by means of phenol; it appeared to be a product in which the concentration of solids was reasonably consistent from batch to batch. It was relatively highly purified, the extract from 100 g. of liver containing only 10 to 15 mg. of solids. The extract normally produced a satisfactory response when 4 ml., derived from 200 g. of original liver, was given in a single injection—that is, a satisfactory response was obtained by a solution containing approximately 25 mg. of solids. However, some batches did not give such a good response on this dosage, while others gave a good response with a smaller dose. The reasons for these variations in activity were traced by an extended investigation of the whole process, and they were virtually eliminated by more precise control at all stages of the fractionation. This led to the production of batches which consistently gave satisfactory responses to a total dose of 4 c.cm., though we also had evidence that a lower dose would suffice in some cases.

The difference between the efficacy of "crude" and "refined" extracts when expressed in terms of original liver will be noted. Whereas "crude" extract derived from 60 g. of liver produced a satisfactory response, "refined" extract from nearly 200 g. of liver was required.

Any or all of three possible causes for the discrepancy might be operative. First, activity might be lost in side-fractions arising during the refining processes; secondly, activity might be destroyed in the later stages of fractionation; thirdly, the haemopoietic activity of liver extracts might be dependent on the simultaneous presence of more than one substance—as postulated, for example, by Jacobson and Subbarow (1941)—and some of these other factors might be removed in the later stages of fractionation. However, investigation showed that appreciable losses of activity were in fact occurring at two stages of the process, and further research indicated a method of avoiding these losses by modifying the conditions of adsorption and elution used in the original Laland and Klem process (1936).

The product of this modified process gave a satisfactory response on a dose derived from 80 g. of liver (all of three cases tested), and the response to lower doses is now being examined. To date, one case has given a satisfactory response on a dose derived from only 60 g. of liver.

It can thus be seen that there is now no discrepancy between the response to "refined" and that to "crude" extract. Moreover, in the modified "refined" extract only 30 to 35 mg. of solids are obtained from each 100 g. of original liver, so that again approximately 25 mg. of solids will give a satisfactory response. Hence the amount of active material extracted from a given weight of liver has been markedly increased without reducing the activity per milligramme of the final extract.

Purification of Liver Extracts

We have recently prepared, by a modification of the Laland and Klem process (1936) involving selective aqueous alcoholic elution of the charcoal adsorbate, a fraction (L.E. 90B) which has produced in two cases of pernicious anaemia satisfactory responses with a total dose of only 5.5 mg. of solids; this dosage was arbitrarily given in 2 ml. of solution. The graphs showing the responses obtained in the two cases are reproduced in Figs. 1 and 2. The tests were carried out by Dr. S. C. Dyke, of the Royal Hospital, Wolverhampton, to whom we are indebted for permission to reproduce the charts. The fraction has since been further purified by means of ammonium sulphate precipitation to give material of which 2.8 mg. produced a response just failing to satisfy the criteria.

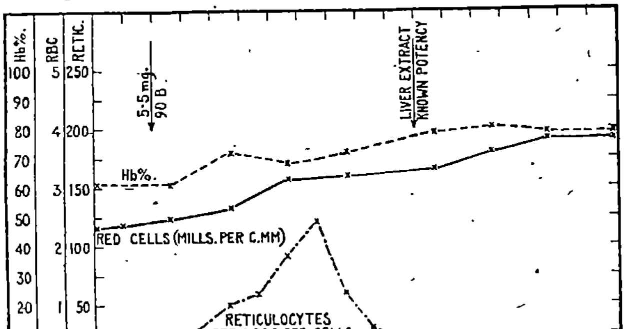

FIG. 1

These fractions compare favourably with the purified fraction described by Karrer (1941), which he reported as possessing "maximal" activity in a single dose containing 15 mg. of solids and "very good" activity in a dose containing 7.5 mg. of solids.

Relation of Volume to Dosage

Some recent medical textbooks (Witts, 1941; Beaumont and Dodds, 1943) indicate, and apparently many clinicians in this country recommend, that any liver extract, no matter of what type, should be given in a certain dose volume (e.g., 2 ml. or 4 ml. twice a week) in order to produce a satisfactory remission of pernicious anaemia and its allied conditions. Dyke and Della Vida (1942) have adopted it as an arbitrary criterion that any liver extract producing a good response with a total dosage of less than 10 ml. over the first fortnight should be regarded as sufficiently potent for therapeutic use. However, it must be quite clear that with a product like the original "refined" extract described above, for example, the solids content (25 mg.) of 4 ml. of solution could quite easily be concentrated into 1 ml., or even 0.5 ml., or, on the other hand, be diluted to 10 ml. It was decided to make the improved "refined" extract recently developed of such a strength that 1 ml. was derived from 100 g. of liver. At this concentration 0.6 to 0.8 ml. can produce a satisfactory response, as indicated above, but the use of 1 ml. provides a margin of safety that adequately covers any small batch-to-batch variations of potency and any losses on storage. This could obviously have been 0.5 ml., 2 ml., or any other volume convenient for injection.

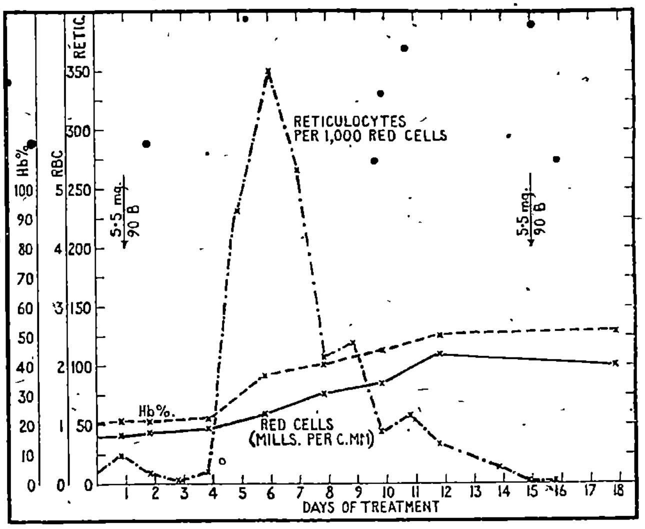

FIG. 2

So far as we have been able to ascertain, no better initial response is likely to be obtained in a normal uncomplicated case of pernicious anaemia by giving larger doses than those necessary to produce a satisfactory response as defined above. In cases complicated by subacute combined degeneration of the spinal cord or nutritional deficiencies larger doses may, however, be required: this can usually be ascertained by careful control of the blood count throughout the period of treatment.

Unit of Activity

We have shown above that different liver extracts should not be compared either in terms of dosage by volume or in terms of the liver from which they are derived, but that the soundest basis of comparison is in terms of their therapeutic activity. Anti-anaemic activity, however, can only be measured by tests on human patients with uncomplicated pernicious anaemia, and the errors involved in such a method of assay are large. Nevertheless, such clinical tests have been adopted as an assay method, albeit a rough one, in America and Canada, and units have been defined in terms of which the activity of all liver extracts must be expressed before they are marketed.

The American (*U.S.P.*) unit depends on the response given by small daily injections of the extract over a period of 15 days. This response is normally assessed on not fewer than three patients by the U.S.P. Advisory Board, who then assign a unitage to the extract. Thus, if a daily injection of 1/15 ml. produces a response considered satisfactory, the extract is given a rating of 15 units per ml. (*J. Amer. pharm. Ass.*, 1940).

The Canadian unit, only recently adopted, depends on the response produced over the first four weeks of treatment by weekly injections. The unit is defined as one-seventh of the weekly dose of extract required to produce a satisfactory response. Thus, if weekly injections of 0.5 ml. will produce a satisfactory response, the extract is given a rating of 14 units per ml.

For the purpose of expressing relative potencies of extracts in this paper we define an arbitrary unit based on the method of testing more generally used in this country. This unit depends on the production of a satisfactory response over 2 weeks following one or more initial injections given within the first 2 days of treatment. Like the Canadian unit, it is expressed as the number of days of treatment (14) divided by the number of millilitres of extract given. Thus, if a single injection of 1 ml. of an extract produces a satisfactory response over the whole of the first two weeks it is said to contain at least 14 units per ml. If another extract has been shown to produce a satisfactory response on injection of (say) 2 ml. on day 1, followed by a further 2 ml. on day 2, it is said to contain at least 14 divided by 4=3½ units per ml. If it can be assumed that a number of small daily injections are utilized as efficiently as the same total dosage given in one or two larger injections at the beginning of treatment, the arbitrary unit defined above is approximately equivalent to the *U.S.P.* unit.

If it can be found possible to give official recognition to some unit similar to that which we have defined we believe it will be of considerable help both to the clinician and to the manufacturer.

Purification Index

Having expressed the potencies of different extracts in terms of a common unit, the relative degrees of purification can be readily examined by determining their content of solids. A convenient "purification index" (P.I.) is obtained by dividing the number of units of activity in each millilitre of the extract by the solids content, expressed as fractions of 1 g. per ml. Such a method of expressing degrees of purification in terms of arbitrarily defined units per unit weight of solids has long been adopted with other biologically active substances before their isolation in pure form—e.g., several of the vitamins, enzymes, pituitary hormones, antibiotics. In these instances, however, potency could be determined by animal assay or microbiological assay, and by increasing the number of replicates used a more or less accurate estimate of the activity could be obtained. Liver extracts, on the other hand, can be assayed only on human cases, of which but a limited number are available; in consequence, the values so obtained will be subject to considerable experimental error, but they will at least indicate the relative orders of purity of the extracts. A few such figures, calculated from known data, are given below as examples:

Extract	Approx. Minimum Dose giving Optimal Response (ml.)	Units/ml.	Total Solids Content (g./ml.)	Purification Index (units/g.)
Original refined extract ..	2–4	3·5–7	0·0075	500–1,000
Modified refined extract	0·6–0·8	17·5–24.	0·035	500–700
Crude extract ..	4–6	2·3–3·5	0·25	9–14
American (15 *U.S.P.*)* ..	1	14·0	0·18	Ca. 80
" "* ..	1	14·0	0·075	Ca. 200
Experimental fraction (L.E. 90B) ..	2	7·0	0·0027	Ca. 2,600

* These figures are based on the assumption that the *U.S.P.* unit is approximately equal to the unit we have defined.

The difference between the "refined" and "crude" extracts is brought out clearly in the above table, "crude" extracts having purification indices of the order of 10, and "refined" extracts (though differing among themselves to a remarkable degree) indices of the order of 100 or more.

The preparation of Dakin and West (1935) has been referred to, though not by the authors themselves, as though it were the actual pure anti-anaemic factor. This, however, gave, at a dose of 80 mg., responses that, judged from the published clinical data, may be regarded as satisfactory in the sense used in this paper. Now, this dose contains approximately 4 units of activity, and is therefore equivalent to a purification index of the order of 200. It seems obvious, from the data obtained with our fraction 90B, that the pure factor must have a purification index of at least 2,500.

General application of this method of expressing the activity of liver fractions would allow papers describing the purification of the active principle to be more critically compared. This presupposes, however, the existence of a common unit of activity.

Maintenance

It is usually found that the blood of patients who respond satisfactorily to an adequate initial dose is brought rapidly to normal by fortnightly injections equal in amount to the initial injection. Presumably, therefore, the average daily requirement during this phase of treatment is 1 unit. The dosage required for the maintenance of normal red-blood-cell levels is very much more difficult to assess. Before any reliable conclusions can be drawn it is necessary to have observations on a large group of cases carefully controlled over a period of several years.

While it may be argued that the ease and cheapness of treatment with modern liver extracts make the measurement of minimal maintenance requirements a matter of somewhat academic importance, such an investigation might well lead to data of considerable practical value. For example, it is not impossible that the incidence of systemic reactions to the injection of liver extracts may be related to prolonged administration of excessive doses. Further, in this country there is a body of opinion that "crude" extracts have advantages over "refined" extracts for maintenance, though recent American publications have claimed that "refined" extracts are as effective as "crude" extracts both for maintenance and for initial treatment (Evans and Jordan, 1941; Murphy and Howard, 1939).

An investigation of minimal maintenance requirements of the "crude" extract, referred to above, has been reported to us by Dr. J. Mills, of the Royal Berkshire Hospital, Reading, and we gratefully acknowledge his permission to summarize his findings here. In a group of 75 patients with pernicious anaemia, a few of whom showed neurological symptoms, about 90% were maintained at levels of 5 million red cells per c.mm. and 100% haemoglobin for periods ranging from 6 months to more than 2 years on a dose derived from 20 g. of original liver (2 ml.), given at intervals of 4 weeks. Those not maintained by this dosage have, without exception, been satisfactorily maintained by a dose derived from 40 g. of original liver (4 ml.) every four weeks, for periods ranging from 8 to 18 months. Hence a dose of the "crude" extract containing approximately 5 units of activity per month appears to satisfy the need of most patients, while one of 9 units per month satisfies the needs of all.

The dose recommended by American authorities for satisfactory maintenance is usually of the order of one unit of activity per day—i.e., 28 units every 4 weeks. We have some evidence, though as yet inadequate, that a dose containing some 17 units of the newly developed "refined" extract, referred to above, is enough to keep patients' blood normal, but tests with a lower dosage have not as yet been carried out.

It is not impossible that the "crude" extract may contain factors of importance in maintenance which are not measured in tests on patients in relapse. Careful comparison of minimum maintenance requirements of "crude" and "refined" extracts in terms of units as discussed here should provide useful information on this point. Similarly, consideration on a unitage basis of dosage requirements in the treatment of the more complex macrocytic anaemias might lead to a resolution of the divergent views (Wills and Evans, 1938; Foy and Kondi, 1939; Hamilton Fairley, 1940; Trowell, 1941; Sundaram, 1944) which are at present held on the relative efficacy of "crude" and "refined" extracts.

Summary

Statements commonly used in this country to describe injectable liver extracts are criticized.

The chief differences between "crude" and "refined" injectable liver extracts and their uses in the initial treatment and maintenance of cases of pernicious anaemia are discussed.

An arbitrary unit of haemopoietic activity, and a "purification index" based on it, are defined.

Attention is drawn to some advantages which would result from the establishment of an official unit of haemopoietic activity in this country.

The relatively low order of purification of commercial "refined" liver extracts is demonstrated by the description of a laboratory

preparation capable of producing a satisfactory response on a total dose containing only 5.5 mg. of solids.

THE PROPHYLAXIS OF RICKETS BY SINGLE MASSIVE DOSES OF VITAMIN D

BY

DAVID KRESTIN, M.D., M.R.C.P.

In an earlier paper (Krestin, 1944) it was shown that rickets still presented a problem in infant entrants to Preston wartime nurseries, for, although severe and advanced degrees of this disease were extremely rare, an early or mild variety was found in 37% of all admissions under 2 years, while in the poorer parts of the town this figure was even higher. Furthermore, it was noted that the free distribution of cod-liver oil for the infants before their admission to the nurseries did not produce any obvious reduction in the incidence of this disorder. Similarly, in a recent report by the Ministry of Health (1944) describing a widespread survey including Great Britain and Ireland, it was found that 73% of the infants with radiologically active rickets had received cod-liver oil or other vitamin D preparation for some period before the investigation, and Corner (1944) found the incidence of the disease in hospital patients actually higher in those who had previously received vitamin D supplements than in the average series. Since the antirachitic value of cod-liver oil is now beyond doubt, and has been shown to be reliable when given regularly and in large enough doses in these nurseries (Krestin, 1945), it is evident that the disappointing results obtained by these mothers in their own homes were due to irregularity of administration and inadequacy of dosage.

For these reasons it seemed desirable to investigate the possibility of a method of preventing the disorder that could be used independently of the mother and yet not require the daily attendance of the child at a clinic or medical centre.

Previous Work

Although Vollmer in 1928 (quoted by Vollmer, 1939) showed that rats which had been fed on a rachitogenic diet could be protected against rickets by a single massive dose of vitamin D, this observation was not applied clinically until 1938, when Harnapp (1938a, 1938b, 1939), in Germany, found that infants under 18 months could be protected during the winter months by single oral doses of 7.5 or 10 mg. of either vitamin D_2 or D_3 dissolved in oil. These results were soon after confirmed in that country by Schwartzer (1939), Rietschel, *et al.* (1940), Hartenstein (1940), and Heisler (1940), most of whom favoured the view that, whereas 5 mg. was too small, 7.5 to 10 mg. was sufficient for the purpose, and that larger doses were unnecessary. Less constant results were obtained by Windorfer (1938) and Brockmann (1938). More recently Wolf (1943) and Rambar *et al.* (1943), in America, reported the results of using single doses of 15 mg. of "ertron," an electrically activated preparation of ergosterol; although in both cases the numbers of infants followed up for five months or more were small, the results obtained were very satisfactory.

Present Investigation and Results

This investigation concerns full-term infants and children between 2 months and 3 years of age, of average health, and showing no radiological or clinical evidence of rickets on admission to ten day and three residential wartime nurseries in Preston. All lived under similar conditions, received similar diet, and were under constant supervision. The period of observation began during the autumn of 1943, and lasted for 6 months throughout the following winter and early spring. After admission each child was clinically examined and then sent for radiographs of the lower ulnar epiphyses. A single dose of 7.5 mg. of calciferol—i.e., 300,000 i.u. of vitamin D_2 dissolved in 1 c.cm. of arachis oil—was then given by spoon after a milk feed, the amount having been measured in a graduated Record syringe. The oil was readily taken by all ages, and, except for vomiting in one small infant, was not followed by any gastro-intestinal disturbance or other unpleasant effects. Thereafter each child was clinically examined at regular intervals of 4 weeks or less, and at the end of 6 months another radiograph was taken of the wrist. Owing to the distance of the nurseries from the *x*-ray centre it was not possible, except in a few instances, to have radiographs taken at more frequent intervals. Biochemical examinations of the blood were not practicable. Throughout the period of observation no other vitamin D preparation was given, nor was any child in this series exposed to ultra-violet radiation.

About one-third of the infants had received some cod-liver oil before admission. The doses were small, and often irregularly given. As the subsequent results in these infants did not appear to differ from the results in those who had not previously received any vitamin D preparation, they are not tabulated separately.

At the same time and during a similar period of the previous year two other groups of infants and children living under exactly similar conditions and receiving the same diets were studied. One, a "control" group, received no vitamin D preparation; the other received daily doses of the Ministry of Food cod-liver oil. The results obtained in these two groups have been discussed elsewhere (Krestin, 1945), but the figures are included in the accompanying Table for comparison.

The diagnosis of rickets in these nurseries has been discussed in earlier papers. The radiographic changes at the lower ulnar epiphyses have been clearly described by Wimberger (1923), A. F. Hess (1930), and others, and so require no further discussion here. It should, however, be noted that in mild rickets of short duration obvious alterations in the appearance of the *x*-ray films may not occur, or may last for so short a time that they may be overlooked unless radiographs are taken at frequent intervals. Craniotabes—i.e., asymmetrical softening of the cranial bones in the region of the lambdoid suture—was found to be a reliable sign in infants older than 3 months, but was rarely found after the sixth month. After the fourth month the most reliable sign, when scurvy could be eliminated was a definite enlargement of the costo-chondral junctions of the fourth to the tenth ribs. Moreover, this sign was of par-

Table showing Comparison of Results after Antirachitic Prophylaxis with Single Massive Doses of Vitamin D_2 and after Daily Doses of Cod-liver Oil, with a Control Group of Infants

Age Groups:	0 to 6 Months			6 to 12 Months			1 to 2 Years			2 to 3 Years

2 dr. = 1,500 i.u. (approx.)	28	3	25	28	2	26	55	6	49	63	0	63
3 dr. = 2,100 i.u. (approx.)	—	—	—	15	0	15	11	1	10	—	—	—
4 dr. = 3,000 i.u. (approx.)	—	—	—	—	—	—	44	0	44	60	0	60
Controls (no vitamin D) ..	14	12	2	30	18	12	28	3	25	15	0	15

ticular value, since, once having appeared, it would last for weeks or months after all x-ray signs of activity had gone. Thus, the appearance of either of these clinical manifestations was accepted as evidence of rickets even with a normal x-ray picture. Similarly, even in the absence of clinical signs, the appearance of definite radiological changes was regarded as diagnostic.

The results obtained are shown in the Table. The most significant figures are those in the group under 1 year, which, as may be seen from the control series, shows the greatest liability to the disease. The figures in the 2–3-year age group are probably without significance, since the controls show that if a child living under the conditions obtaining in the nurseries can avoid the disease during the first two years of life it will probably remain free after that age even without special prophylactic treatment. Compared with infants receiving regular daily doses of cod-liver oil, the results of administration of a single massive dose of vitamin D_2 are satisfactory, the failures being 3 out of 43 infants under 12 months and 3 of the 93 infants under 2 years. Thus the claim of earlier workers in Germany and America appears to be substantiated.

Discussion

Mode of Action

Windorfer (1938) found that after a single large oral dose of vitamin D dissolved in a small amount of oil 93% was absorbed from the bowel. There is, so far, little evidence in the literature as to the exact fate of the vitamin after its absorption. By feeding large doses of this vitamin to rabbits Warkany (1936) and his colleagues (Warkany, Guest, and Grabill, 1942) were able to produce a rise in the blood level from the average normal of 50 i.u. to 2,700 i.u. in 24 hours, which was maintained for about 4 days before slowly returning to normal in 4 to 6 weeks. In human subjects they found that after stopping the daily administration of larger doses the serum level of vitamin D remained above normal for from 3 to 6 months. Further, Heymann (1936, 1937) showed that after large doses were given to rabbits the vitamin could be demonstrated in the tissues and organs for varying periods, and for as long as 12 weeks in the liver and plasma. Thus it would seem that after a single large dose the organism is able to draw on a store of this vitamin for some 8 to 12 weeks. By this time the growing animal has probably been able to lay down enough calcium at the metaphysis to last throughout the winter, though it may be advisable in the case of infants, particularly those under 1 year, to repeat the dose after 3 months if the first one was given in the autumn or winter—i.e., before the beginning of March.

Possible Disadvantages: Toxicity of Vitamin D

Except for one instance of an infant who vomited the dose and was then quite well, no ill effects of any kind were observed among those who received the single dose of 7.5 mg. This was equally true in a further series of infants with active rickets (not reported here) receiving single doses of 15 mg. (i.e., 600,000 i.u.). Further, subsequent radiographs of the non-rachitic infants did not show any noticeable increase of calcium deposition at the metaphysis. Similarly, complete freedom from unpleasant after-affects was noted by all the earlier workers referred to above.

A considerable amount of recent work has shown that most of the undesirable manifestations previously observed after relatively small doses of vitamin D were due to toxic substances produced by the over-irradiation of ergosterol. With more recent methods of preparation these substances are not produced, and the material supplied is almost pure calciferol. With preparations of this kind, Bills and Wirick (1930) found that amounts over 4,000 times the minimal antirachitic dose were required to produce even mild manifestations of toxicity in the case of rats. Catel and Pallaske (1931) and Pallaske (1932) could find no injurious effects at necropsy after very large amounts given to goats and other animals. In infants, J. H. Hess *et al.* (1930) found that daily amounts up to 50 times the ordinary prophylactic dose could be continued for months, and up to 250 times this dose for short periods, without ill effect. Steck *et al.* (1937), after extensive work with dogs and human subjects, concluded that 20,000 i.u. per kilogramme of body weight could be given daily for indefinite periods with impunity, but with doses greater than this undesirable symptoms might follow. After amounts up to 1,000,000 i.u. given by mouth or by intramuscular injection to premature infants, Zelson (1940) failed to find evidence of damage to tissues at necropsies where death resulted from intercurrent infection. Rambar *et al.* (1943) failed to find any persistent rise in the blood levels of the calcium or phosphorus after single oral doses of 15 mg. (i.e., 600,000 i.u.). After the daily administration of from 20,000 to 40,000 i.u. for 6 months to a premature twin, however, Ross and Williams (1939) reported the appearance of anorexia, loss of weight, and vomiting, ending in death; at necropsy there were bronchopneumonia and extensive calcification of arteries, heart muscle, kidney, stomach, and lungs.

It may therefore be concluded that the amounts of vitamin D used in this study are well within the limits of safety, and that, where necessary, they could be repeated once or twice during a period of 6 months without ill effect. There is, however, some evidence that metastatic calcification may occur with much lower doses in the presence of renal disease. In such circumstances it would probably be advisable, for the present, to use the older routine of small daily doses.

Wolf (1943) states that ertron is less toxic than irradiated ergosterol. This substance is not at present available in this country.

Absence of Vitamin A from Preparation

As the preparation used in the single-dose method contained no vitamin A, these infants differed from those receiving daily cod-liver oil in that they were deprived of this added vitamin as well as of the daily supplements of oil. Although it was the general impression in the nurseries that these infants remained well and thrived satisfactorily, it was thought advisable to compare their progress as regards weight, height, and incidence of infection with the control and cod-liver-oil groups. This is shown in the diagrams. As growth is more rapid during the first year of infancy, separate diagrams are given for those under 1 year, and for those over 1 year but not exceeding 2 years, at the end of the six-months period of observation.

Weight.—It will be seen (Fig. 1) that in those over 1 year there is little difference in the average gain in weight in the three groups. Thus infants receiving no vitamin A or D or oil, and those receiving vitamin D only, seemed to thrive as well as those getting daily oil containing these vitamins. The infants under 1 year who received the daily oil appeared to gain less than the other two groups. This unexpected result may possibly be explained by diminished alimentary absorption following the daily administration of two doses of oil, since there seemed to be no reduction in the amount of feed taken by these infants.

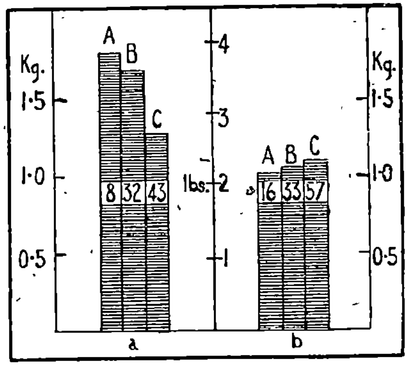

FIG. 1.—Average gain in weight after six months. A, Controls. B, After receiving single dose of vitamin D. C, After receiving daily doses of cod-liver oil. a, Under one year. b, Over one year. Figures within columns show number of infants.

Height.—Fig. 2 shows the average gains in height. It will be noted that neither the control nor the single-dose group show any disadvantage compared with those having the daily supplements.

Infection.—Records of all infections were kept on charts showing the duration of illness in days for each child. As the influence of age, immunity from previous attacks, and the opportunity for contact are doubtless predominating factors in the acute infectious or specific fevers, these are omitted from consideration. For similar but somewhat different reasons, the incidence of gastro-intestinal and skin infections is also not discussed. It was thought that the average number of days of illness due to infection of the upper and lower respiratory tracts—i.e., nasopharyngeal, tracheo-bronchial, and pulmonary infections—would provide some guide as to the susceptibility of each group. Infection was recognized by the appearance of definite clinical manifestations, including a rise of rectal temperature to 99.6° F. or more.

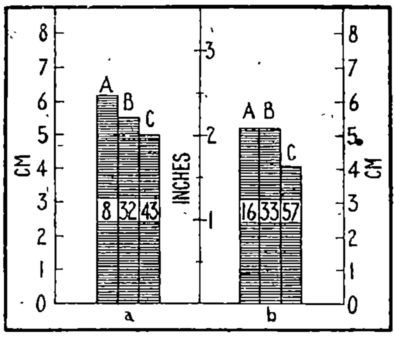

FIG. 2.—Average gain in height after six months

The average number of days of illness for each group is shown in Fig. 3. It will be seen that there is a lack of consistency in the two age groups. In those under 1 year the cod-liver-oil group has a lower average than have the other two groups. In those over 1 year, the lowest average is found in the single-dose group. This difference cannot be explained, and is presumably due to chance.

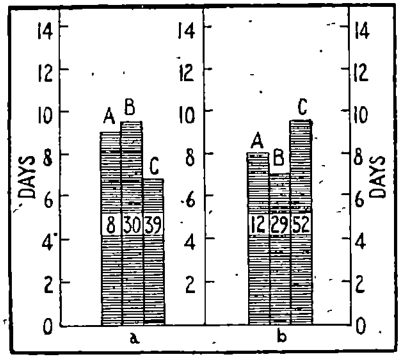

FIG. 3.—Average number of days of illness due to infection of the upper and lower respiratory tracts during period of six months.

Owing to the fact that many of the controls under 1 year developed manifestations of rickets and received treatment for this before the end of the six-months period of observation, the numbers on which the averages are based in this group are small, so that undue significance cannot be attached to them. Nevertheless, the other columns in the diagrams suggest that the infants who received the single oral dose of vitamin D were at no obvious disadvantage compared with those who received the daily cod-liver oil. This is not altogether surprising, for while retarded growth and increased liability to infection may result from gross vitamin-A deficiency produced under experimental conditions, there is no definite evidence that real benefit follows the addition of this vitamin to an already adequate diet in infants showing no signs of such deficiency. Obvious manifestations of vitamin-A deficiency are probably uncommon in infants and children living under moderately healthy conditions; none was noted in any of the entrants to these wartime nurseries, and they would not be expected to appear on the diets there given.

It should be mentioned that all infants, including the controls, received the Ministry of Food orange juice every day.

Advantages of the Method

These for the most part are obvious and require little discussion. The chief of them is that an infant can be given a single small dose of oil by a trained nurse at an out-patient clinic, welfare or other medical centre, and then need not be seen again for two or three months. The method is thus largely independent of the mother. A very considerable quantity of oil is saved, which, besides being more economical, may be a factor of importance in wartime. In the case of residential or day institutions where large numbers of infants have to be cared for, the reduction in work is greatly appreciated by the staff. Further, this method is particularly suitable for feeble infants, for those liable to gastro-intestinal disturbances, or for those who for any reason are unable to take daily doses of oily preparations. Park (1940) has drawn attention to the danger of lipoid pneumonia from aspiration of oil given frequently or in large quantities to weakly babies or those liable to vomiting.

Although this paper is concerned with healthy full-term infants, it is relevant to mention that where, ordinarily, larger amounts of vitamin D are required, as in premature babies, those recovering from marasmus or acute illness, or those who are taking thyroid, the dose with this method would require increasing and probably repeating. Thus a premature baby would probably need an initial dose of 15 mg. followed by one or two further doses of 7.5 mg. during the winter and spring months.

It is claimed by some workers (Hess and Lewis, 1933; Rietschel *et al.*, 1940; Hartenstein, 1940; and others) that for the prevention of rickets in infants vitamin D_3 is superior to D_2. The evidence for this at present, however, is not convincing. The available supply of vitamin D_3 in this country was insufficient for any large-scale investigation.

Summary and Conclusions

The prophylaxis of rickets by means of a single massive dose of vitamin D_2 given by mouth was investigated during a period of six months of the autumn, winter, and early spring in 137 infants under 3 years, and the results compared with controls who received no vitamin D preparation and infants who received daily doses of the Ministry of Food cod-liver oil.

Of 93 infants under 2 years who received one dose of 7.5 mg. (300,000 i.u.) 90 remained free from the disease throughout the period of observation.

A short review of the literature is given, and the possible disadvantages and advantages of this method are briefly discussed. The freedom from all ill effects is noted.

It is suggested that when a child first comes under observation in the late winter or spring—i.e., after the beginning of March—one dose of 7.5 mg. is probably sufficient. If first seen before this time, it would probably be wise to repeat the dose after 3 months.

Premature infants, those taking thyroid, and those growing rapidly after marasmus or an acute illness may require double the above doses, possibly repeated at shorter intervals.

I am greatly indebted to Dr. F. A. Sharpe, medical officer of health, for allowing me to carry out this investigation, and for permission to publish this paper; to Dr. J. Laurie, medical superintendent of Sharoe Green Hospital, for the *x*-ray facilities; and to Miss P. Wright and the matrons of the nurseries for their zealous co-operation. I wish also to thank Glaxo Laboratories Ltd. for the generous supply of the vitamin used.

PROPHYLAXIS OF RESPIRATORY TRACT INFECTIONS WITH SULPHANILAMIDE LOZENGES

BY

A. F. HAYDEN, M.R.C.S., L.R.C.P.
Captain, R.A.M.C.

AND

JOSEPH W. BIGGER, M.D., Sc.D., F.R.C.P., F.R.C.P.I.
Lieut.-Colonel, R.A.M.C.

Percy Garson (1943) claimed that a significant decrease in the incidence of infections of the upper respiratory tract could be effected by the administration of small amounts of sulphanilamide in lozenges. In view of its possible value in the Army, it was decided to investigate this method of prophylaxis on a larger scale than Garson had found possible. Messrs. Boots Pure Drug Co. Ltd. kindly supplied two types of lozenges. One (yellow) consisted of 2 g. of lozenge basis, and the other red) of the same weight of basis in which was incorporated 0.065 g. of sulphanilamide.

Individuals vary greatly in the time for which a lozenge could be made to last, the average being about 20 minutes. An estimate of the concentration of sulphanilamide in the saliva of a subject sucking a red lozenge which lasted for 20 minutes was made by pooling four samples of saliva ejected at 5-minute intervals. The concentration of sulphanilamide was found to be 300 mg. per 100 c.cm. of saliva. This might be expected to have considerable local action, but it is improbable that the dose (0.325 g.) swallowed in 24 hours could have any general action.

The population used in the investigation consisted of 1,200 recruits receiving instruction in a primary training centre (P.T.C.). These men had within a few weeks been transferred from civil to Army life, and experience has shown that infections of the respiratory tract very often occur soon after exposure to the communal existence of the Army. The recruit normally spends six weeks in the P.T.C., and while there belongs to one of three companies—A, B, or C. At the beginning of his training he is allocated to one of the six barrack-rooms which accommodate the personnel of each company. The investigation dealt with five groups of men, each from a separate intake, and, to secure uniformity, each company was included at least once and the investigation covered various stages of the six-weeks training period. The men in each barrack-room were divided into two sections, to one of which red (sulphanilamide) and to the other yellow (control) lozenges were administered for a period of 16 days. Table I gives the essential facts about the composition of the population investigated.

TABLE I

Group	Company	Month	Week of Training in which Investigation Began	Number of Men on Each Type of Lozenge			
				1–9 Days		10–16 Days	
				Sulpha	Control	Sulpha	Control
1	A	March	Fifth	103	103	89	85
2	C	April	Third	136	139	120	126
3	B	May	„	119	124	96	107
4	A	June	„	119	114	114	115
5	C	June	First	105	131	107	121
			Totals ..	582	611	526	554

Total numbers { Sulphanilamide .. 1,108 ; Control .. .. 1,165 } 2,273

Lozenges were distributed by an N.C.O. at 06.30, 11.00, 13.30, 7.00, and 20.30 hours daily for 16 days. The men were instructed to begin to suck the lozenges immediately they were received, to make them last as long as possible, and to swallow their saliva while they remained in the mouth. The medical officer (A. F. H.) who was completely in control of the collection of data did not know, until the investigation had been concluded, which type of lozenge contained sulphanilamide. The men knew nothing of the composition of the lozenges.

On the ninth and again on the sixteenth day after administration of lozenges had started, the company was assembled and divided into two groups—red and yellow. Only men who had regularly taken lozenges during the preceding 9 or 7 days and were present on parade on the appropriate day were included in the investigation. Owing to postings, absences, defaulters, etc., not every man included in the first period was included in the second, but the great majority were. A very few men included in the second period had not been included in the first because they had been absent from the first parade.

The information abstracted in Table II was derived from the answers given by the men to carefully designed questions. It represents, therefore, the opinions of the men concerned on their symptoms.

Table III gives details of the illnesses of the men who reported sick with signs or symptoms of respiratory tract infections during a period of 14 days starting two days after administration of lozenges had begun. Apart from temperatures and the results of auscultation, the data were supplied by the men themselves in response to carefully designed questions.

TABLE II.—*Symptoms Reported at End of 9 and of 16 Days*

	Red (Sulphanilamide Group)	Yellow (Control Group)
Number of men in group ..	1,108	1,165
Slight cough	585	493
Severe „	70	121
Nose blocked	228	249
„ running	303	342
Painful to speak	95	92
„ „ swallow	70	71
Malaise	81	91
Fresh or increasing cold during previous 7 days	237	351
Without cold	398	396

TABLE III.—*Men Reporting Sick during Last 14 Days of Administration of Lozenges*

	Red (Sulphanilamide Group)	Yellow (Control Group)
Average strength	555	584
Number reported sick	60	66
Temperature over 99°	10	6
Rhonchi at one or both bases ..	6	4
Cough	55	55
Headache severe	6	6
„ moderate	7	14
„ slight	3	6
Nose blocked	26	24
„ running	21	31
Malaise	13	12
Painful to speak	23	21
„ „ swallow	21	30
Duration of cold before reporting sick:		
0–7 days	51	52
8–14 days	8	11

Discussion

The only figures showing statistically significant differences in the two groups (Table II) are those for coughs (slight and severe) and for fresh or increasing colds during the previous 7 days. If we are prepared to place complete reliance on statistical theory, we are forced to believe that the administration of sulphanilamide in the form of lozenges reduces the incidence of severe coughs and of fresh or increasing colds, but we are equally forced to believe that it increases the incidence of slight coughs.

We prefer—as we believe most of our readers will—to conclude that the protection against infections of the respiratory tract afforded by sulphanilamide lozenges, if indeed there is any such protection, is so trifling as to make the method of prophylaxis not worth the trouble, expense, and slight risk involved.

REFERENCE

Garson, P. (1943). *British Medical Journal*, 2, 452.

H. F. Fernandes (*Tubercle*, 1944, 25, 82) records six illustrative cases of bilateral tuberculous effusion (five of them fatal) in patients aged from 15 to 37 which occurred among 2,012 admissions to the Derbyshire Sanatorium during the period 1938 to 1944. Five showed radiological evidence of miliary tubercle during the final stage of fluid resolution, and one developed a tuberculous spine some time afterwards.

RECOVERY FROM DIABETIC COMA OF ABRUPT ONSET WITH EXTREME HYPERGLYCAEMIA

BY

CHARMIAN ELKES

House-physician, the Diabetic Department, King's College Hospital

Exceptionally high blood sugars in coma have been recorded both in this country and in America. The highest figures quoted by Joslin (*Treatment of Diabetes Mellitus*, 7th ed., Henry Kimpton) are 1,850 mg. per 100 c.cm. in a case of Dillon and Dyer's which recovered, and 2,060 mg. in a fatal case reported by Lawrence. The following case in which the blood sugar rose to 1,960 mg., occurring in a young woman with no previous history of diabetes, is of interest.

Case History

A married woman aged 31 was admitted to King's College Hospital on June 28 as an air-raid casualty. She was quite conscious, had slight superficial wounds of the scalp and left thumb, and, although not shocked, appeared to be anxious. A radiograph of the skull showed no fracture. The routine ward report states that no reducing substances or ketone bodies were found in her urine, but, as the ward was extremely busy at the time, it is not possible to be absolutely certain of this point. On the 29th she vomited her breakfast, and during the day passed 82 oz. of urine, which was not tested. During the following night the nurse reported that the patient had collapsed suddenly with a low-volume pulse, but had recovered rapidly without treatment.

On the morning of the 30th she vomited again and became restless and increasingly drowsy. The knee- and ankle-jerks were absent, but her disks were normal, and the C.S.F. was normal and under normal pressure. During the afternoon she became increasingly restless, then delirious, and finally comatose. At that time she was extremely dehydrated, a smell of acetone was noticed in her breath, and she had air hunger. Up to midday she had passed 51 oz. of urine, but subsequently had to be catheterized. At 6 p.m. her urine was found to be loaded with sugar and ketone bodies, and to have a trace of albumin; chlorides were absent. She was immediately given 60 units of insulin subcutaneously, and a 4% glucose-saline intravenous drip was started. Blood was taken from her ear by capillary pipette, but owing to the dehydration a small amount clotted and the blood-sugar reading of 998 mg. per 100 c.cm., which was estimated by the Folin-Wu method, was certainly inaccurate. 100 units of insulin were given intravenously at about 6.30 p.m., and the glucose-saline drip was changed to one of normal saline. At 7 p.m. blood from the ear was taken easily and the blood-sugar reading was 1,960 mg. per 100 c.cm.

The following Table shows the response of the patient to treatment in the next 48 hours. The restless mania was very troublesome, and has occurred occasionally in other cases of diabetic coma treated in this clinic.

Date and Time	Urine		Blood Sugar (mg./100 c.cm.)	Insulin (Units)	Remarks
	B.	R.			
June 30					
6 p.m.	+ + + +	+ + +	? 998	60 100 i.v.	Eye tension very low. 4% G.S. drip started. Very slow. Changed to normal saline
7 p.m.			1,960	200 i.v. 200	
9 p.m.			1,960		Becoming maniacal. Less air hunger
12 p.m.	+ + + +	+			Very noisy. Sod. amytal 7½ gr. i.v.
July 1					
3 a.m.			1,360	60	Very noisy. Sod. barb. 3 gr. i.m.
4 a.m.					Very restless. Morphine ¼ gr.
7 a.m.					" " " "
8 a.m.	+ + + +	Trace	250		Quieter. Less dehydration. Normal respirations
11 a.m.				40	
3 p.m.					7th litre normal saline completed. Changed to 4% G.S.
4 p.m.	+	Trace	89		45 g. glucose added to drip fluid. Consciousness returning
8 p.m.					I.V. therapy discontinued. 5% G.S. run. P.R. for a few hours
10 p.m.	+ + +	Trace	222	20	
July 2					
2 a.m.	Trace	+			
6 a.m.	Trace	+ + +			Glucose drinks started
10 a.m.			392	20	
2 p.m.	+ + +	0		20	20 g. carbohydrate 2-hourly by mouth from now onwards. Much better

B.=Benedict's test. R.=Rothera's test. G.S.=Glucose-saline.

The patient improved rapidly and was taking food at ordinar times on the third day after the onset of coma. Three weeks late she was discharged on a diet containing 180 g. of carbohydrate and a mixed dose of 16 units of P.Z.I. and 28 units of solubl insulin. She has had much the same dose ever since, and is quit well.

Past History.—It was only after recovery that the past histor could be obtained. She had never been ill, and gave no famil history of diabetes or any previous frank symptoms of diabetes except perhaps an occasional "dryness" of the mouth at night The relation of her very sudden coma to her slight air-raid traum remains obscure.

I wish to thank Dr. R. D. Lawrence and Dr. W. G. Oakley fo their help and encouragement in publishing this case.

Medical Memoranda

Unusual Cause of Death in Carcinoma of Cervix

As an appendix to Mr. Foster's records of two cases of adenocarcinoma of the small intestine (*Journal*, 1944, **2**, 78), I woul like to describe a case of intestinal obstruction due to a secondary deposit of a squamous-celled cervical carcinoma.

Case History

Female, aged 52, married, 11 children; admitted to Lurgan District Hospital April 11, 1944. Her only previous illness was "gall-stone" operation many years ago (details of this were no available). She complained of irregular and fairly smart vagina bleeding for 6 weeks and attacks of epigastric pain, with vomiting and aggravated by food, for 6 months. Apart from some tenderness in the epigastrium, nothing abnormal was found on clinica examination. Vaginal examination revealed a hard area in th cervix. *Biopsy of this enabled a diagnosis of cervical carcinoma* Stage I or early Stage II, to be made.

The patient was then transferred to the Royal Victoria Hospita Belfast, with a view to radium therapy. There she underwent Wertheim's hysterectomy, and was discharged on June 2 feeling ver well. At operation the bladder was found to be adherent to th front of the uterus at the junction of the body and cervix. Ther were a few nodules on the posterior surface of the cervix; ther was also an enlarged gland in the left parametrium. Histolog revealed that the adhesions to the bladder were infiltrated wit malignant cells. The diagnosis was thus squamous carcinoma o cervix, early Stage IV.

Two days after discharge from Belfast she was readmitted to medical ward in Lurgan Hospital, complaining of colicky epigastr pain and vomiting. The possibility of biliary colic was considere and she was kept under observation. She went out against advic on June 17, her condition being almost unchanged. Five day later she was readmitted to Lurgan Hospital still complaining o abdominal pain, with copious vomiting of brownish-green materia The *diagnosis of small-gut obstruction* was made, and after fiv pints of glucose-saline by intravenous drip had been given laparotom was carried out. The ileum was greatly distended and many vascul adhesions were present in the pelvis. These were divided, but wer considered insufficient to cause an obstruction. About an inch fro the ileocaecal valve was a hard annular stricture which complete occluded the ileum; distal to this the gut was normal. An ile transversostomy was performed and the abdomen closed. Unfortunately the patient died in 6 hours (48 days after hysterectomy).

A very limited post-mortem examination was carried out and th growth removed. The peritoneal coat and mucous membran appeared intact, but the lumen would admit a match-stick only wit *difficulty. The muscle coats were infiltrated with a whitish substance* which apparently did not involve the peritoneum or th mucous membrane. Histology revealed this to be a squamous-celle carcinoma.

Discussion

Apart from the single gland in the left parametrium, n evidence of secondary deposits *in the gut or elsewhere* wa found at hysterectomy: the ileocaecal region was not spec ally examined. *It is possible that the long history of epigastr* pain and vomiting was due to subacute intestinal obstructio which finally became acute, causing the terminal symptomat logy.

The problem to be solved is the determination of the mo of spread. Was it due to implantation during hysterectomy- via the lymphatics of the retroperitoneal tissues or via th blood stream?

I am indebted to Mr. Bassett and Mr. Macafee for permission to publish t details of this case.

J. STANLEY ELWOOD, M.B.,
Formerly R.M.O., Lurgan Hospital.

Reviews

GENETIC AND ENVIRONMENTAL FACTORS IN DISEASE

Psychosomatic Diagnosis. By Flanders Dunbar, M.D., Med.Sc.D., Ph.D. With foreword by Leonard G. Rowntree. (Pp. 741. 37s. 6d.) New York: Paul B. Hoeber, Inc.; London: Hamish Hamilton Medical Books.

Human Constitution in Clinical Medicine. By George Draper, M.D., C. W. Dupertuis, Ph.D., and J. L. Caughey jun., M.D., Med.Sc.D. (Pp. 273; illustrated. 21s.) New York: Paul B. Hoeber, Inc.; London: Hamish Hamilton Medical Books.

hese two books are in a sense complementary. Dr. Flanders unbar lays stress on the environmental factor in disease, while r. Draper emphasizes the genetic one. Both, however, agree their main conclusions. If Paracelsus and van Helmont ere to return to earth they would doubtless be surprised find, in a greatly changed medical world, a revived interest their conception of the Archaeus, the "sensitive soul" housed the solar plexus. Psychosomatic medicine is its modern uivalent: to-day we must discard the idea that any disease wholly physical or wholly mental. This psychosomatic proach is only new in the sense that it attempts to substitute scientific basis for things sensed intuitively by the older ysicians. Dr. Flanders Dunbar in a detailed study of the bject recalls Sherrington's dictum that essentially the mind bserves an inhibitory function in relation to behaviour, and at the greatest relief of instinctual tension is provided by tion, the least by fantasy and thought, whereas speech stands alf-way between. In this connexion the degree and type f the patient's muscular tension, whether in postural attitude, ice, or gestures, particularly in their variations according the matter under discussion, may be revealing if sometimes fficult to evaluate. Such tensions, as we know, can express emselves in visceral as well as in somatic muscles, thus producing organic symptoms. It is significant, in the present state f the world, that the use of the word "tension" has spread r beyond its scientific connotation into all forms of literature. efore psychosomatic medicine could pass from a merely intui-ve to a scientific stage much, as the author points out, had be accomplished in the basal sciences of anatomy, physiology, athology, and clinical medicine; and it is only half a century nce Freud with Breuer put forward their views on the psychic echanism of hysterical phenomena, while the explanation of eneral paralysis as an organic disease distinct from other sychoses is still more recent. Small wonder then that we are ill only on the margin of the subject, which will continue revolutionize our conception of disease as we emerge from e too materialistic attitude of the recent past.

Dr. Dunbar's book is a painstaking, conscientious account f her twelve years of research along these lines. There are any interesting things in it, particularly her full discussion f the psychology of the "accident-prone." The interweaving f psychical traumata with the development of physical signs clearly indicated. But we must confess that the book would ave appealed more if not elaborated in quite so much detail, nd if there was less use of the scientific jargon which defaces much medical "literature."

This objection cannot be lodged against Dr. George Draper nd his associates, Drs. Dupertuis and Caughey. The introduc-on to their book is attractively written; indeed sometimes they rite so persuasively as almost to lull our critical sense into ccepting the anthropometric standards at which Dr. Draper as worked so assiduously for many years. Yet we recall e late W. F. R. Weldon's biometric studies, which have roved less fruitful than their author hoped. An actuary can retell with a considerable degree of accuracy the prospects f survival for two million persons of a certain age, but he annot prophesy the fate of a single individual. In the same ay physical measurements can give an average formula for ose liable to develop peptic ulcer, gall-stones, pernicious naemia, and so on, but individualism will assert itself in sease as in health. Indeed the authors appear to forestall is criticism when they say (p. 154): "Although results btained by averaging the observations made on a large series f people have value, the striking of an average tends to sub-erge the individual quality of the diverse organisms that comprise the group." But, be it noted, they make this comment in the section on constitutional physiology, where they seem prepared to allow for more individual variation than in morphology. Indeed the sections on the physiological aspect and its clinical application to work are full of practical wisdom. Particularly we would commend the stress laid on the training of the student's power of direct observation—a power which is too often allowed to remain dormant. Insistence on attention to the patient as an individual and not a mere vehicle for a disease can never be made too strongly. The philosophic outlook of the chapter on "Growth, Development, Decline, and Death" should arouse the interest of even sluggish minds. Throughout we are given a very high ideal of the role of the physician, leading to the conclusion that "the fine technique of the initial approach to the person must be wrought from special qualities within the personality of the doctor and through his cultivated talents."

Theories, like words, have their vicissitudes. Fifty years ago the word "diathesis," despite its respectable ancestry, had fallen into disrepute under the impact of the laboratory. "Constitutional diseases" figured in the textbooks as a synonym for some diseases of unknown causation. But genetics and the study of inborn diseases soon showed the way to a more exact investigation of the constitutional factor, which was later reinforced by the psychological approach. Of the interest which has been evoked by the resulting impulse to treat the patient as an indivisible unit these two books are abundant evidence.

MASSAGE

Deep Massage and Manipulation Illustrated. By James Cyriax, M.D., B.Ch. (Pp. 242; illustrated. 15s.) London: Hamish Hamilton Medical Books. 1944.

This is essentially a book for the physiotherapist. The technique devised by the author is very fully described; the illustrations are excellent and demonstrate clearly his method and the conditions for which it may be used. A brief introduction is worthy of study by doctors who prescribe massage, for although the author states, "It is no part of the medical practitioner's duty to supervise the massage technique employed," there is no doubt that doctors ought to have some practical acquaintance with the scope and limitations of physiotherapy, and should, when prescribing massage, indicate clearly the object it is desired to attain. It is not unknown for massage to be prescribed for conditions for which it is unsuited or to the wrong parts, as, for instance, in sciatic pain originating in the gluteal muscles when massage is ordered for the sciatic nerve itself, where it can do no possible good. The author does not attempt to describe the technique of all forms of massage and limits himself in this book to deep friction, which if used intelligently in the way he advocates is likely to give gratifying results in cases which are often difficult to treat and may indeed lead to permanent disability. A point of some interest, departing from the common practice, is the author's view that heating should not precede deep massage but may follow it, and for this he gives sound reasons. Teachers of massage as well as students will find this book instructive and stimulating.

TUBERCULOSIS OF EAR, NOSE, AND THROAT

Tuberculosis of the Ear, Nose and Throat; including the Larynx, the Trachea, and Bronchi. By Mervin C. Myerson, M.D. (Pp. 291; illustrated. $5.50 prepaid or 30s.) Springfield and Baltimore: Charles C. Thomas; London: Baillière, Tindall and Cox. 1944.

Dr. Myerson writes on tuberculosis of the ear, nose, and throat from special experience gained at the Sea View Hospital, and his views therefore compel respect. A large part of the book is devoted to the larynx, and although this is satisfying it contains nothing original, and he adheres strictly to orthodox lines of treatment, relying much, as did Sir StClair Thomson, on the use of the cautery. Dr. Myerson's opinion upon the effect of pregnancy is expressed fully in a special chapter, and he takes a much less gloomy view of this combination than was formerly prevalent. No doubt many pregnancies have been terminated unnecessarily on this account, and the author's discussion gives valuable guidance on this difficult question. A notable section of the book deals with tuberculosis of the middle ear and mastoid process—an obscure and frequently overlooked lesion on which there is much illuminating information illustrated by good pathological material.

Lupus, apparently, is much less common in America than in Europe, and Dr. Myerson claims only a very small clinical experience of this form of tuberculosis. The most original part of the book is that in which tracheal and bronchial tuberculosis is described along with an account of bronchoscopy in this particular connexion. This is a recent application of the bronchoscope, and the views expressed upon its use and abuse are a valuable guide. Writing of the tongue it is stated that at the Sea View Hospital sections were made of 200 tongues, and 19.9% were affected with tuberculosis. This statement is repeated later in the book, so that it is apparently not merely a slip of the pen, but it is difficult to understand how the author arrived at this calculation. He has, however, produced a comprehensive and well-documented account of the subject based on a large personal experience, and those interested in tuberculosis will be grateful to him. There are numerous illustrations, most of which convey their meaning clearly enough but have little aesthetic merit, and their artistic level does not rise to the literary standard of the text.

Notes on Books

A third edition of *Aids to Materia Medica*, by Dr. GEORGE H. NEWNS, has been published by Baillière, Tindall and Cox at 5s. The author of this small book can be congratulated on having produced a very useful collection of information, which includes the essential points of the actions of most of the substances considered. For the student wishing to prepare for an oral examination it should be valuable.

The appearance of a fifth edition of Dr. WILLIAM BROWN'S *Psychology and Psychotherapy* 24 years after the first bespeaks its continued popularity. Dr. Brown is dogmatic and persuasive, and in his writing does not employ too many technicalities. He follows no particular school and has theories of his own. He has enjoyed a deserved reputation as a successful psychotherapist and so is well equipped to appeal to the public in his writings. The first part of the book deals with the theories of psycho-analysis in relation to his own and relates some of his experiences in treatment. There is a new chapter on alcoholism which does not present anything specially new. The other new chapter is on the psychology of modern Germany, in which he traces the philosophical background of Nazi doctrine, then traces Hitler's own psychological development, classing him as both a paranoid and a hysteric. He considers that the German people as a result of their reactions to their defeat in the last war have identified themselves with Hitler's mentality and are also paranoid and hysteric. The chapters on the relation of mind to brain and on psychical research are little altered. Dr. Brown favours Bergson's philosophy and retains an open mind on but continued interest in spiritualism. The book is published by Edward Arnold at 14s.

Lieut.-Col. B. W. RYCROFT'S unambitious little book, *A Manual of Ophthalmology for Medical Officers* (Hamish Hamilton Medical Books; 10s. 6d.), should prove of considerable value to medical officers in the Services. The author devotes the introductory third of his text to methods of examination, to a description of standard lesions, and to an excellent general summary of the various methods of treatment employed. This makes the rest of the book easy to understand and apply. A final chapter deals with the special eye problems seen on active service. The many tables and summary classifications should be an extra help.

The Surrey Benevolent Medical Society was founded in May, 1812, by a meeting of doctors held at Epsom. It was at first of a social nature with a scientific side, exemplified by papers and discussions on medical subjects. As money accumulated the charitable side grew, and to-day the benevolent fund stands at over £24,000 in addition to the possession of four perpetual scholarships at Epsom College, bought in 1855. Dr. A. R. Walters of Reigate, one of the vice-presidents, has prepared a pamphlet which begins with a history of the founder, Thomas Martin, and follows with extracts from the minute-book giving a view of development and progress. The society helps doctors who are in need with the education of their children and the support of their families. Though the financial position is now very strong more members are needed. The hon. secretary is Dr. L. J. Barford, Heather Lodge, Redhill.

Dr. J. WILSON REID, honorary medical officer of H.M.S. *Conway*, has compiled a pamphlet, *Emergency Treatment of the Injured and Sick at Sea*, to meet primarily the needs of cadets training for sea service. It includes notes on further treatment when medical aid is unobtainable, for guidance in exceptional circumstances where there is no hope of the casualty receiving medical attention for some co siderable time. These notes are printed in italics and clearly mark so that such guidance may not be misused. The pamphlet published at 2s by Charles Birchall and Sons, Ltd., Liverpool a London.

Preparations and Appliances

USE OF SYNTHETIC MATERIALS FOR SURGICAL DRAINAGE

Mr. STEWART MANN, M.B., F.R.C.S.ED., assistant surgeon t out-patients, Glasgow Royal Infirmary, writes:

Improvement in surgical technique now makes the necessi for drainage less than in former times; and the dange attending the indiscriminate insertion of foreign bodies in wounds for this purpose have been emphasized by Kanave Trueta, Watson-Jones, and other writers; but there are sti many indications for their employment, and great quantiti of natural rubber are consumed. This material, the conserv tion of which has been repeatedly stressed by the Combine Raw Materials Board, has not been surpassed by any oth since it was introduced by Chassaignac in 1859. In virtue its resilience, flexibility, and capacity to transport blood an inflammatory products, it has gradually superseded the catg strands of Cheine, the soft lead tubes of Bell, and the resorbe tubes of Neubauer, which were responsible for MacEwen development of the decalcified chicken-bone drain.

A satisfactory drainage tube must be flexible without kinkin too easily. It requires to be light in weight, non-adhesive, no toxic, easily sterilized and cut, and not too easily compresse by heavy flaps or sutured wound edges. It is a desirable featu that the end in contact with the tissues of the body shou be soft enough to minimize trauma or necrosis. Exceptin rubber, there are few materials capable of fulfilling all the requirements; but we believe that there are possibilities in th field of synthetic plastics, and the two types described belo have been used by us extensively during the past two years.

Resinized Cotton Tubes.—These are constructed of finely wove cotton impregnated with a resin which does not crack or flak When the tube is bent, the interstices of the woven fabric are com pressed on one side and opened out on the other—a design whic confers a limited flexibility. These tubes, well known in the electric industry, are marketed under various names and can be sterilized boiling. Samples that had been autoclaved in the usual way ga no growth of bacteria after five days' incubation in anaerobic flu media. They are prepared for use by immersing one end for fi minutes in a 1 in 20 solution of carbolic acid to dissolve the res from the walls so as to allow the part in contact with the tissues t exert the capillarity conferred by its texture and to stimulate loc reversal of the lymph circulation in the sense described by Horsle and Whitehead. This procedure is essential to soften the end t be inserted. The tubes can then be boiled, cut, shortened, an adapted, and may be stitched in position. Though these tubes ar cheaper than corresponding rubber ones, they are not nearly s flexible and, being easily kinked, are unsuitable for abdomin surgery. In spite of these limitations, they have been used wi advantage in the out-patient department of our unit for nearly tw years.

P.V.C. (Polyvinyl Chloride) tubes are composed of a plastic manu factured by heat extrusion. They have physical properties whic render them almost indistinguishable from tubes of natural rubbe The P.V.C. tube is unaffected by age, water, salt solutions, bile, pu or body fluids, inorganic acids and alkalis, or mineral oils. The can be manufactured in all colours and in various grades of thick ness and flexibility, according to specification. They have been use with success in all cases where rubber drainage tubes were formerl used, including drainage of the pelvis, gall-bladder, and peritone and pleural sacs. It should be noted that immediately after steriliza tion by heat they may become too soft for general use, but wi regain their original texture after immersion for a few minutes i cold saline solution.

Though recommended as a wartime emergency measure, it i believed that more lasting advantages may result from the adoptio of tubes prepared from synthetic materials for purposes of surgica drainage. I wish to express gratitude to Mr. George Swanso visiting surgeon, Glasgow Royal Infirmary, who supervised their u in his unit, for helpful suggestions and advice; and to the Duratub Co., Middlesex, for supplies of material.

ENERIC AND SPECIFIC TRIVIAL NAMES OF HE MALIGNANT TERTIAN AND QUARTAN MALARIA PARASITES

BY

FRANCIS HEMMING, C.M.G., C.B.E.

Secretary to the International Commission on Zoological Nomenclature

he *Official List of Generic Names in Zoology* was established y the International Congress of Zoology in order to promote ability in zoological nomenclature by placing on record the orrect names of the principal genera in each of the classes nd orders of the animal kingdom, together with their type pecies. Hitherto names have been placed on the *Official List* *Opinions* rendered by the International Commission on oological Nomenclature, but in 1943 the International Comission decided that it was desirable to make the *Official List* iore readily available, and accordingly determined to publish it s soon as possible in convenient book form and with a full idex. The preparation of the *Official List* for publication in iis way, which was begun in the autumn of 1943, involved ie checking of all the relevant bibliographical and other refernces to the generic names concerned and their type species. 1 the course of this work, errors were detected in a number f the *Opinions* containing decisions relating to the *Official List.* hese errors are being brought at once to the attention of the iternational Commission with a view to their rendering an *pinion* as soon as possible containing such rectifications as iay be necessary.

Among the errors detected were errors in the entries in *pinion 104* (published in 1928) relating to the author's name nd date of publication of the generic name for the malignant rtian malaria parasite (*Laverania* Feletti and Grassi, 1889). urther, in the case both of this name and of that for the uartan parasite (*Plasmodium* Marchiafava and Celli, 1885) the ype species was found to have been cited under a name which as not the correct name under the International Code of oological Nomenclature. The names of these parasites, as ecorded in *Opinion 104,* are the names now universally mployed for these species in the enormous medical and chnical literature relating to malaria, and it would clearly e as wrong as it would be impracticable to attempt to introuce changes in such names merely on grounds of zoological omenclature. In the present case such changes would be articularly undesirable, since they would involve the transfer f the specific trivial name "*malariae*" from the quartan arasite (on which it was bestowed by Grassi and Feletti, 1890), y which name this species is universally known, to the ialignant tertian parasite, on which in 1881 it had been idependently bestowed by Laveran (and by which name this pecies is never called). Transfer of trivial names in this way iuses great confusion, and the only solution in such a case for the International Commission to use its plenary powers suspend the rules in order to validate the names currently use. It was accordingly decided early in 1944 to invite the iternational Commission to deal with this question under its enary powers, and for this purpose a thorough investigation to the highly complicated literature of these names was made, ith the assistance of Sir Rickard Christophers and Brig. Sinton, whose paper "The Correct Name of the Malignant ertian Malaria Parasite," published in the *British Medical urnal* (1938, **2**, 1130), must form the starting-point of any ork on this subject. In the course of this investigation names eviously overlooked were brought to light and other unispected nomenclatorial difficulties were disclosed. A paper tting out in detail the present position under the International ode and containing recommendations to the Commission for acing the whole matter on a satisfactory footing has been epared and will appear in the next Part of the *Bulletin of oological Nomenclature,* the official organ of the International ommission on Zoological Nomenclature.

Quite recently the Officer in Charge of Malaria Control in ar Areas, Atlanta, Georgia, U.S.A., communicated to the ternational Commission an application prepared by Drs. urtis W. Sabrosky and Robert L. Usinger, U.S. Public Health Service, drawing attention to the errors in *Opinion 104,* and requesting the International Commission to use its plenary powers to suspend the rules for the purpose of validating existing nomenclatorial practice in regard to these parasites. This application has since been published in the issue of *Science* of Sept. 1, 1944. It is extremely gratifying to the Executive Committee of the International Commission to find that malariologists in the United States, working independently, have reached substantially identical conclusions in regard to this matter, since this should greatly facilitate the early adoption by the International Commission of an *Opinion* setting this matter at rest once and for all.

In order to secure the widest support for the action proposed to be taken, the Executive Committee, on behalf of the International Commission, invites expressions of opinion from specialists concerned in any aspect of the malaria problem. Such communications, which should be addressed to the International Commission on Zoological Nomenclature at its Publications Office, at 41, Queen's Gate, London, S.W.7, will at once be published in the Commission's official organ, the *Bulletin of Zoological Nomenclature,* in order that the whole of the material relating to this case may be before the Commissioners when reaching their decision.

ANGLO-AMERICAN CONSULTANTS CONFERENCE

A conference unique in the annals of medical meetings took place in Brussels on Dec. 10 and 11 under arrangements made by the Director of Medical Services, 21st Army Group, with the assistance on the professional side of Brig. A. E. Porritt, Consulting Surgeon, Brig. E. Bulmer, Consulting Physician, and Col. J. S. K. Boyd, Deputy Director of Pathology. Over 50 consultants—American, British, and Canadian—from the Forces in N.W. Europe attended, with representatives of the War Office and of Canadian Medical Headquarters. This followed a similar meeting in Paris in October, 1944, organized by Major-Gen. P. R. Hawley, Chief Surgeon, European Theatre of Operations, U.S. Army, which proved so valuable that further meetings were thought necessary in order to integrate the professional work of the several Armies.

The proceedings in Brussels comprised a combined meeting of physicians and surgeons, followed by meetings of medical and surgical sections. The subjects discussed were: Chest wounds (Major J. L. Collis, R.A.M.C.), uses of penicillin (Lieut.-Col. G. A. G. Mitchell, R.A.M.C.), personal re-allocation (Lieut.-Col. W. R. Lewin, R.T.R.), dermatology (Lieut.-Col. F. F. Hellier, R.A.M.C.), Weil's disease (Brig. E. Bulmer, R.A.M.C.), diphtheria (Major-Gen. A. G. Biggam), prevalent diseases (Col. W. S. Middleton, U.S.A.M.C.), paraplegics (Brig. G. Riddoch, R.A.M.C.), abdominal wounds (Col. Elliott Cutler, U.S.A.M.C.), anaesthetics (Lieut.-Col. R. M. Tovell, U.S.A.M.C.), vascular injuries (Lieut.-Col. C. B. Odom, U.S.A.M.C.), head injuries (Brig. H. W. B. Cairns, R.A.M.C.), burns (Lieut.-Col. E. M. Bricker, U.S.A.M.C.), joint injuries (Lieut.-Col. A. L. Eyre-Brook, R.A.M.C.)

Throughout the conference there was a remarkable absence of diversity of opinion, though there was a very free interchange of views and experiences. Many of the problems of war medicine and surgery have such important implications that they cannot be ventilated publicly, while their successful solution is, at times, more valuable to the Allies than the enemy's "secret weapons" are harmful. Such an opportunity for pooling knowledge as this conference afforded is of inestimable value to the war effort, and achieves not only this immediate purpose but helps to pave the way to the establishment of that international understanding and unity of purpose which must in due course be the keystones of a successful peace.

A small committee has been set up in Edinburgh to organize a memorial to Dr. Andrew Graham Ritchie, F.R.C.P.Ed., who died on Oct. 12, 1944. It is proposed to provide a bursary to be awarded annually to a medical graduate of Edinburgh University. The award will be based on character rather than on educational attainments, and preference will be given to the son or daughter of a member of the medical profession.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY JANUARY 20 1945

THE WATCH ON LONDON'S WATER

One of the outstanding public health achievements of the war has been the protection of London's water supply. Seven years ago, owing to the accidental contamination of one of its wells, Croydon had an outbreak of typhoid, with 323 cases and 43 deaths, and public alarm and indignation were widespread. But if, through the hazards of war, only one of the twelve filtration works of the Metropolitan Water Board had become a source of infection, the result, calculated on the basis of previous epidemics, would have been an outbreak fifty times greater than that of Croydon, not to speak of hundreds of permanent carriers to form a reservoir of fresh infection. The calamity not only to public health but to public morale can be imagined. In fact not a single case of typhoid attributable to the water supply has occurred in London since September, 1939. The water supply of the immense metropolitan area must have seemed as obvious and desirable a target for the enemy as the wells of Moab to the predatory children of Israel. To stop or to pollute the water supply of one-sixth of the people of this country would have been a paralysing blow in total war, worth many military victories. The metropolitan water system covers an area four times the size of the Isle of Wight and serves seven million people, to whom it brings a daily average of 300 million gallons. To distribute this water through 8,000 miles of pipes is far more than a gigantic piece of plumbing. Five-sixths of the supply is river water, which becomes more and more heavily polluted and has to undergo most elaborate purification; while the remaining one-sixth, from the wells of the great chalk basin beneath London, is progressively deteriorating with increased urbanization, and must be chlorinated. Continual examination and analysis is necessary.

To use a phrase which has quickly become hackneyed, "it can now be revealed" what precautions the Metropolitan Water Board took during the years of war. A part of the revelation was made in a recent lecture at the Royal Institution by Lieut.-Col. E. F. W. Mackenzie, director of water examination, who now fills the office which Sir Alexander Houston occupied with far more than local renown for thirty years. Every conceivable form of damage was done by aerial attack, though apparently most of it was incidental. Sewers were damaged during every raid, with the result that untreated sewage was discharged into the river from which the raw water supplies came. Reservoirs were cut off from purification works by the destruction of aqueducts. Bombs fell into filter beds and caused short circuits between filtered and unfiltered water channels. The demand for water against fire necessitated the occasional by-passing of the slow sand filters in order that supplies might be maintained. Fracture of water mains was an almost inevitable accompaniment of heavy aerial bombardment; o one night alone five hundred mains were broken. Ye though the opportunities for dangerous pollution wer manifold, London escaped any epidemic. During fou years of war bacteriological analyses were carried out o more than 50,000 samples drawn at the works, particularly in localities where bomb damage had been heavy, an 99.3% showed absence of *B. coli* in 100 ml.—in othe words, the water conformed to the highest standard o bacterial purity.

How this achievement was brought about is in many way technical and to be appreciated only by the water enginee In the first place it was determined that there should b no interruption in the routine of laboratory examinatio and quality control. Suitable buildings in comparativel safe areas were converted into accessory or alternativ laboratories. Pre-chlorination, in high dosage when necessary, was extended to all the filter works, thereby makin it certain that the water was in a state of considerabl bacterial purity before it even reached the filters. Th residual chlorine in the water passed into supply wa increased to the highest level consistent with avoidance o serious complaint on the ground of taste. By this mean the danger of bacterial pollution through seepage o ground water into broken filtered water channels was, i not neutralized, at least greatly reduced. But the presenc of this residual chlorine in the water was not made a excuse for relaxing the more positive methods of protection. Chlorination is ordinarily regarded as only th third in importance of the purification processes, the firs two being storage in large reservoirs and filtration throug slow sand filters, though it was foreseen that at any momen the circumstances of war might make chlorination th most important, or even the only, barrier against th spread of water-borne disease. Chlorine installations wer duplicated at convenient points; provision was made fo applying chlorination where no apparatus had existed, an mobile chlorinators were also brought into use and assigne to different areas in London.

The possibility of chemical poisons being introduced int the water, either deliberately or accidentally by the use o poison-gas bombs, was countered by a system of guard at the works and reservoirs and by arrangements fo immediate testing on suspicion of contamination. A sta of sample collectors and analysts was employed at th central laboratories day and night to carry out confirmator tests. The ever-present danger of the admission of th contents of sewage channels into water channels owin to the fracture of both was provided against by the us of valves which permitted of rapid closure in emergenc and by a thorough flushing and disinfection of any mai after repair and before it was brought back into suppl To add to all this it must be remembered that it was no only for purity but for plenty that the Metropolitan Wate Board had to strive. In heavy raids local destructio caused occasional interruption of water supplies, and on of the most heartrending things was to see fire spreadin from house to house, as we saw it in one cherished district of old London, with the firemen standing helplessly b because the water supply was exhausted. It must hav een a heavy responsibility to decide how far orthodox nethods of purification might be discarded with a view o increased production. It was constantly a choice etween two very different but heavy risks—and there is o hard-and-fast line between a safe and an unsafe water, ny more than between a state of health and of disease.

Those in charge of London water have written a great ew chapter in public health history during the last five ears, but like so many chapters of the kind, because the eaten adversary was largely unseen, because the possible alamity never took shape, it goes largely unread. The itizen will still go to his tap and turn on the water of the hames or the Lea, and expect to find it pure and tasteess for drinking and plentiful and clear for cleanliness, nd will have something to say about it if it is not. The chievement will be written off as just another piece of onstabulary duty—the sort of thing one has a right to xpect of a British public service; and that, indeed, is the ighest compliment that can be paid to it.

THE MEDICAL FILM

he Scientific Film Association is to be congratulated on aving made a start with the organization and co-rdination of medical cinematography. The purpose of he medical film is quite different from that of the enterainment film, and it is important that they should not e confused. Otherwise comparisons are inevitably drawn vhich are inappropriate, because the two types of film hould be used in an entirely different way; nothing is nore tedious than an unbroken succession of medical or cientific films. We therefore strongly recommend the cientific Film Association at once to give up any idea f medical film shows and not to repeat the type of rogramme presented at the meeting held at the Royal ociety of Medicine on Dec. 7. This programme conained four films. The first dealt with the removal of a hell fragment from the heart; it was of no scientific alue, and its proper place was in a news reel or magaine programme at a public cinema. The second dealt vith the genesis of function in the embryo; it was highly echnical, dealing with actual research, and was incomrehensible without a detailed verbal introduction. The hird was a straightforward teaching film on spinal anaeshetics. The fourth dealt with the survival and revival of rgans and organisms; it had far-reaching implications or surgery and philosophy and would have served as the ntroduction to an enthralling debate. All this was packed nto 90 minutes. It would not be unfair to say that the rogramme had attracted the wrong kind of audience—an udience interested in means rather than ends. It left an ffect of acute fatigue and confusion. Such a programme nay have been thought necessary as providing an initial llip to the study of the scientific film. In itself, however, contributed nothing to the understanding of the place f the film in medical teaching, and it may, in fact, have onfirmed some people in the opinion that the scientific lm is an extra-curricular activity, to be classed with party olitics and amateur theatricals, all of which merely lure he student from the straight and narrow way.

The film may be used in medicine for public propaganda, for undergraduate and postgraduate teaching, or for the presentation of the results of research. We shall forgo discussion of medical propaganda films except to say that we believe that, like medical broadcasting, they are of tremendous importance in the education of democracy, and the best brains in medicine should be prepared to collaborate in their production. In the narrower field concerned with the showing of films within the profession, what is needed is actual demonstration of how to use the film in teaching and how to use the film to present the results of research. How helpful are the scabies films in the teaching of dermatology or the malaria film in the teaching of malariology? Should the two scabies films be given in immediate succession to drive the lessons home? How does Prof. X actually use his series of films of tics and tremors in student teaching? To what extent can we use the film as the gramophone is used for teaching musical appreciation, stopping and repeating until the lesson has been learned? Why was Florey's penicillin film such a brilliant illustration to his address, and was its effect produced by intellectual or emotional means? Can we formulate any general rules for the use of colour and the animated cartoon? The best way to begin attacking these problems may be to create a Section of Medical Cinematography in the Royal Society of Medicine. Such a section would hold two kinds of meetings. There would be combined meetings where methods of teaching would be demonstrated or original work would be illustrated by films. Thus the anaesthetic films would be shown at the Section of Anaesthetics, and discussions would be held to estimate their precise value in the teaching of anaesthetics. The Section of Medical Cinematography would also have its own meetings, at which films were shown and criticized from the aspect of production and technique. Whichever kind of meeting was held, it would rarely be desirable to show more than one film on any single occasion.

As a profession, then, it is high time we got past the penny-gaff state of mind, gave up going to meetings merely to see medical films, and began to wrestle seriously with the problem of the value and methods of illustrating the medical lecture by the new techniques of the cinema film and the sound track. As is pointed out in a recent broadsheet on British documentary films,[1] there is more experience and skill available in this country for the production of scientific and factual films than in any country in the world. Hitherto it has hardly been employed at all in the service of education, and we have the vicious circle that there are no films because the schools do not have the projection apparatus to show them, and vice versa. In an instructive article on medical films[2] Longland, MacKeith, and Stanford have pointed out that the Goodenough Committee gave no consideration to the use of the film in medical schools or to the cost of such a development. It is to be hoped that the medical schools will repair this omission in their discussion of the Report. If the clinical period is to be kept at 2½ years they will have to copy the Services and devise some form of synthetic training in which clinical experience is supplemented by cinematic instruction. What is needed now is not so much technical advances in the production of films as hard thinking and experiment to determine how best to integrate the film with the rest of the apparatus of medical education. Unfortunately the older teachers seem more concerned with the politics of the Goodenough report—the fate of the colleges, the role of the municipal hospitals, and the placement of women students—than with improving the technique of education; and we may have to wait for the younger generation to return from the wars before we can get radical changes in medical teaching.

---

TERMINOLOGY IN MALARIA

For some time terminology in malaria, especially that relating to the epidemiology of this disease, has been in need of revision and standardization to bring it into line with modern conceptions and usage, and, so far as possible, to attain uniformity and precision in the meaning of terms employed by workers of different countries. The Health Section of the League of Nations shortly before the war appointed a committee to consider the standardization of terminology in malaria, and its report has been published. Further, in this number of the *Journal.* Mr. Francis Hemming, Secretary to the International Commission on Zoological Nomenclature, contributes an article on the generic and specific names of the malignant tertian and quartan malaria parasites. These documents provide a clear and useful review of the subject. The report of the Health Section of the League of Nations consists of two parts—a commentary and a glossary of precise definitions. The commentary outlines the chief facts of malaria and its epidemiology, indicates the terms in use, and explains why some of them should be retained or improved upon. A suggestion welcome to the practical worker is that the expressions *vivax* malaria or infection, *falciparum* malaria or infection, etc., should be employed in place of such clumsy and archaic names as "simple tertian," "benign tertian," and the like. The full explanation of what is meant and implied by various indices in use, the treatment of the problems connected with endemicity, and the guidance to the nomenclature of species and varieties of anopheles, should all help to achieve precision and uniformity.

The correct names of the malaria parasites have long been a matter of controversy, and it is here that the communication from the Secretary to the Commission on Zoological Nomenclature promises a satisfactory solution. The names *praecox*, *immaculatum*, *tropica*, and *falciparum* claimed by their respective upholders as carrying priority are none of them seemingly the correct name of the malignant tertian parasite judged by strictly zoological standards. Yet by a sort of irony of error it is impossible now to apply the correct name either to the malignant tertian or to the quartan parasite, because the correct specific name for the malignant tertian parasite cannot be anything else but *malariae*—the name given to it by Laveran, who first described this parasite; the very name that for nearly half a century by reason of an early error has, through a vast literature, been incorrectly used to designate the quartan parasite. It is unthinkable that a change could now be made, and fortunately in such cases the International Commission on Zoological Nomenclature has power to rectify matters by suspending the rules, if necessary, to validate names currently in use. That it is proposed, as will be seen from the Secretary's communication, to exercise these powers will be generally welcomed.

HOUSING THE ROYAL COLLEGES

An article on another page briefly tells the story, so fa as it has gone up to now, of the project to bring togethe on a common site in the middle of London the Royal College of Physicians, the Royal College of Surgeons, and th Royal College of Obstetricians and Gynaecologists. Letter printed in the *Times* last week have put the idea into th foreground. This is a matter of great interest and importance to medicine, and it should have free discussion. Th attitude of the R.C.S. is clear and has been openly state in the annual report. At the annual meeting of Fellow and Members on Nov. 16 the President said, with regar to the rebuilding of the College and the proposal to buil the other Royal Colleges on adjacent sites, that the possibilities of building elsewhere had been explored, but th manifest advantages of the site in Lincoln's Inn Field seemed to outweigh them. Nevertheless the Council o the R.C.S. has said it is prepared to make big sacrifice if convinced that a move is necessary for the promotio of better relations or facilities between the three corporations. It may be supposed that the R.C.O.G. would welcome removal from its house in Queen Anne Street to th large site on the south side of Lincoln's Inn Fields. Mor than fifteen years ago the R.C.P. decided that its buildin in Pall Mall East and Trafalgar Square, which opened i 1825 when the College moved from Warwick Lane in th City of London, was unsuited for its purpose and that new home should be sought. By 1934 negotiations fo the sale of the Trafalgar Square site to the Canadia Government for the enlargement of Canada House wer nearly complete, but had to be broken off. In recent year the Standing Joint Committee of the three Colleges cam to the unanimous conclusion that the securing of a singl site was more important than the qualities of any particula site. Meanwhile the R.C.S. has acquired new ground i Lincoln's Inn Fields large enough to accommodate th needs of all three Colleges as well as a number of th major specialties. A factor which must carry weight wit the Fellows of the R.C.P., on whom rests the responsibilit of decision, is that, in Lord Dawson's words, "the presen Canadian Government is still wishful, subject to negotiation, to purchase the R.C.P. building." The scheme fo adjacent College buildings in Lincoln's Inn Fields may b both practicable and desirable from the point of view o the R.C.P.: it certainly deserves early and careful consideration. There would seem to be much to gain an little to lose if consultants and specialists were topographically conjoined in Lincoln's Inn Fields.

PREVENTION OF BLINDNESS

An intensive sight-saving campaign promoted by th National Institute for the Blind is opening in 1945. Alread the rehabilitation work of the Institute has brought th light of a fuller life to those who labour in physical darkness. Recently the County Councils Association and th Association of Municipal Associations requested the Institute to prepare a minimum scheme of ophthalmologica research, which has been adopted, and presently it i expected that the major local authorities will be invite to support it. Meanwhile, Oxford University Medica School resolved upon establishing a research centre wit Miss Ida Mann at its head. That department has alread done promising work. A fund was opened a year ag and £100,000 has been received from voluntary source mainly industrial. Sir James Marchant, who has bee promoting the Oxford Fund, has now been invited b the Prevention of Blindness Committee of the N.I.B to undertake the founding of a central fund fro which the centres in London, Leeds, and Manchester will largely profit. The results of these research centres will be co-ordinated, and it is confidently expected that in a generation blindness will be much reduced. Writing on this campaign for 1945 Sir James reminds us that ophthalmology as a university subject involves the co-ordinated study of the dominant sense in man in all its aspects—evolutionary, developmental, physiological, psychological, and pathological. The demand for research in industry and medicine is not merely a matter for technical experts: it is a new venture in human thought. He asks that his appeal should not be regarded as a mere matter of charity; it is a business proposition which will pay a handsome dividend. The present aim is to raise £1,000,000. He is to be found at 224, Great Portland Street, London, W.1, or Lenthay Lodge, Sherborne, Dorset.

SCIENTIFIC CO-OPERATION WITH CHINA

Anyone who thinks about China must reflect that famine and disease, both before and during the Sino-Japanese War, have taken a far greater toll of the lives of Chinese babies than have Japanese bombs. It is remarkable that China, after a war of such duration and under such conditions, has continued to manifest even a show of resistance. If sympathy for China is to have value it must be based on a correct interpretation of China's needs. The material aid that can be given to China will continue to be limited by the general war situation, and such is the state of communications that Chinese scientific workers have been cut off from scientific and technical journals and have therefore been unable to follow the progress of science in the West. Some of the barriers to a flow of information on scientific matters between this country and China have recently been discussed in *Nature* and in an article by Dr. Joseph Needham, F.R.S., in the same journal.[1] [2]

Dr. Needham is director of the British Council Cultural Scientific Office in Chungking. The story of the development of this office is told in the Report of the British Council for 1943–4.[3] Dr. Needham arrived in February, 1943, and immediately embarked upon an exacting programme of visits, discussion, and lectures which involved extensive travel under difficult conditions and no little physical hardship. By February, 1944, he had visited over 100 Chinese scientific institutions. Within a few weeks of his arrival he had submitted to the British Ambassador a detailed memorandum which led to the formation of the British Council scientific office which he now directs. Dr. Needham was later joined by Dr. Dorothy Needham, also a distinguished biochemist, and the services of Prof. William Band, a physicist, were loaned by Yenching University, Peiping. More recently Dr. L. E. R. Picken, a Cambridge zoologist, joined the staff in Chungking. Both Dr. J. Needham and Dr. Picken have, in addition to their scientific attainments, been students of the Chinese language and culture for some years.

A few weeks ago Dr. A. G. Sanders, of the Sir William Dunn School of Pathology, Oxford, one of Sir Howard Florey's team of workers on penicillin, arrived in Chungking as medical adviser to the British Council office for a period of not less than one year. Dr. Sanders has had experience both as a clinician and as a laboratory worker, and although he will be concerned with the supply of information on a wide range of medical subjects, his ability to speak as an expert on penicillin—and, particularly, on its non-industrial production with improvised equipment—may have practical significance.

It is satisfactory to note that the *British Medical Journal* is one of many scientific periodicals which the British Council is now sending regularly by air-mail on microfilm. Copies of the journals themselves are necessarily sent by a slower and more uncertain route. Since the establishment of the scientific office in Chungking it has been possible also to meet many requests for books and reprints. It is to be hoped that these efforts will be accepted in China as an expression of the desire of British medical and other scientific workers to offer the fullest collaboration to their Chinese colleagues and to help them to endure for yet a little while that unhappy isolation which circumstances have thrust upon them.

PHARMACOPOEIAL POLICY

The Seventh Addendum to the *British Pharmacopoeia, 1932,* shows a continuation of the progressive policy of the Pharmacopoeia Commission. Among the additions are benzedrine under the pharmacopoeial name of amphetamine, cyclopropane, zinc-protamine-insulin, nembutal under the name of soluble pentobarbitone, and all the sulphonamides with the exception of sulphasuxidine and sulphamezathine. It is interesting that gratus strophanthin (or ouabain) has been included. This is a crystalline strophanthin of constant activity, and it remains to be seen whether doctors will use it more than they have the *kombé* strophanthin, which is already included. The potency of the *kombé* strophanthin was ensured by a biological standardization. Since the introduction of digoxin the profession appears to have neglected the use of strophanthin for injection, though it has considerable value as a heart tonic.

The Addendum contains a large number of monographs for various tablets. Codeine phosphate appears in the *B.P.* not merely as codeine phosphate but also as tabellae codeinae phosphatis, so that each tablet contains not less than 87.5% or more than 110.5% of the prescribed or stated amount: the manufacturer, in making a large batch of tablets by mixture with an excipient, will have to take care that the distribution of the codeine is reasonably uniform in the mixture. Tablets are now official for several barbiturates, sulphonamides, antipyretics, vitamin preparations, and other substances. Provision is made for those doctors who do not state what dose the tablet is to contain, by a statement of what is to be dispensed. "Soluble thiopentone" is another addition of interest, though few will recognize pentothal under this description: the Addendum does not indicate that soluble thiopentone and pentothal are one and the same thing. The *Pharmacopoeia* would help its readers if it published proprietary names as synonyms or else as the names of substances having a very similar action. A large New York hospital recently instructed its dispensary to supply, for all proprietary articles ordered for patients, the equivalent products described in the *United States Pharmacopoeia*; this saved the hospital no less than £12,500 in one year—which shows there is something in a name after all. Dispensers in British hospitals might take a hint, and teachers of clinical medicine might set their housemen an example by eschewing the use of proprietary names when official terms exist: it should be quite simple to call sulphanilamide by its name instead of by one of the numerous fancy terms politely called synonyms.

Prof. G. Grey Turner will deliver the Hunterian Oration before the Royal College of Surgeons of England on Wednesday, Feb. 14. His subject is "The Hunterian Museum: Yesterday and To-morrow."

SUPERVISION OF MENTAL DEFECTIVES IN THE COMMUNITY

BY

J. S. COOKSON, M.D., D.P.H., Barrister-at-Law

Deputy County Medical Officer of Gloucestershire

The object of this communication is to place on record the changes which wartime has brought to those mental defectives who live in the community. This study is limited to those persons ascertained as mental defectives under the Mental Deficiency Acts (1913 and 1927) and therefore under the supervision of the local authority. This supervision was undertaken primarily to provide an immediate remedy where the defective was being cruelly treated or had been left without adequate protection, and also afforded an opportunity to give warning and assistance to the relatives where such were found necessary. The name of the ascertained mental defective is recorded in the National Register as a person not subject to the National Services (Armed Forces) Act, 1939; he is thus able to seek employment on his own without reference to the employment exchange. As a result of shortage of man-power some of those who before the war would have been looked upon as unemployable are now in full work.

To my knowledge no similar investigation has been recorded in the English literature, but Kannar (1942) has drawn attention to the comparable position in the United States of America.

Statutory Supervision

At the beginning of 1944 there were 323 ascertained mental defectives in Gloucestershire subject to supervision by health visitors. This total may be divided for the sake of convenience into three main groups, and it is the third group with which these notes are mainly concerned.

(*a*) *Unsuitable for School (96 Cases).*—These are the youngest cases under statutory supervision, and include children below school age and children of school age who are uneducable either at an ordinary elementary school or at a special school for mental defectives. By reason of mental defect their names were removed from the school registers.

TABLE I.—*Male Mental Defectives under Statutory Supervision*

No.	Age	Mental Age	Source of Ascertainment	Employment
1	29	—	School	Forestry
2	19	8 years	,,	Factory worker
3	18	9 years 7 months	,,	Collier
4	25	8 years	,,	Agricultural worker
5	22	6 years	,,	Coal haulier
6	24	7 years 6 months	,,	Agricultural worker
7	29	7 years	,,	Builder's labourer
8	19	6 years	,,	Factory worker
9	16	7 years 10 months	,,	Agricultural worker
10	32	—	,,	Works at saw mills
11	15	5 years 6 months	,,	Thatcher
12	18	11 years 6 months	,,	Agricultural worker
13	34	5 years 9 months	,,	,, ,,
14	33	8 years	,,	General help at hotel
15	24	9 years 4 months	,,	Lorry driver's mate
16	28	—	M.O.H.	,, ,, ,,
17	22	5 years 2 months	School	Errand boy
18	18	9 years	,,	Agricultural worker
19	17	9 years	,,	Collier
20	19	7 years 3 months	,,	Checker, rlwy. goods dept.
21	22	7 years 6 months	,,	Boot factory
22	30	—	,,	Agricultural worker
23	17	9 years 9 months	,,	,, ,,
24	25	8 years 7 months	,,	Machinist at factory
25	21	—	,,	Agricultural worker
26	22	7 years 6 months	,,	,, ,,
27	39	—	,,	Office cleaner
28	25	7 years 3 months	,,	Haulier
29	31	8 years	,,	Builder's labourer
30	19	8 years 4 months	,,	Agricultural worker
31	38	—	,,	,, ,,
32	20	9 years 9 months	,,	,, ,,
33	26	6 years 9 months	Probation officer	Errand boy
34	24	—	School	Agricultural worker
35	17	7 years 10 months	,,	Hotel kitchen worker
36	16	9 years 2 months	,,	Agricultural worker
37	46	—	—	,, ,,
38	19	5 years	School	Errand boy
39	26	8 years	,,	Agricultural worker
40	39	—	,,	,, ,,
41	23	7 years 6 months	,,	,, ,,

(*b*) *Unsuitable for Work (179 Cases).*—These are usually cared for in their own homes. The parents or relatives with whom they are living find that they can deal with their physical needs, but require a varying amount of guidance and assistance from time to time in dealing with the special problems associated with the mental defect. In addition the occasional contact as provided by the health visitor at quarterly intervals is found to have a stabilizing effect.

(*c*) *Suitable for Work (48 Cases).*—Some 41 males and 7 females were employed in full-time work bringing in a reasonable wage, and 44 of the 48 cases were ascertained from the school records, whereas cases ascertained from other sources did not fit into this group. As will be shown later, this fact is by no means without significance in view of the changes introduced by the new Education Act.

Of 114 males 41 were in gainful employment, and 20 of these were engaged in agricultural work. Many of these men have low mental ages, but inquiry has shown that in spite of this they are able to drive tractors and to perform other tasks of farming which are by no means monotonous. No useful purpose would be attained by drawing attention to occasional cases where the defective was found to be drawing a high wage in a factory, a sum in excess of the wages of the health visitor carrying out the supervision. A defective with a mental age of 8–9 years is able to do certain repetitive work in a factory, but this does not seem to be a state of affairs to be encouraged, by reason of the ever-present danger of powerful and rapidly moving machinery. It is difficult to see how a boy with a mental age of 7–8 years can make a checker in a railway goods department. Even those working as errand boys provide something of a problem, but it has been explained to me that they memorize the whereabouts of the customers without reading the addresses. Those described as colliers were found to be only surface workers employed in sorting and grading the coal.

TABLE II.—*Female Mental Defectives under Statutory Supervision*

No.	Age	Mental Age	Source of Ascertainment	Employment
1	28	—	Public Assistance Committee	Factory worker
2	20	6 years 6 months	School	,, ,,
3	48	—	Public Assistance Committee	Domestic ,,
4	18	8 years 3 months	School	,, ,,
5	31	—	,,	Laundry ,,
6	27	7 years 4 months	,,	Factory ,,
7	20	10 years 6 months	,,	Domestic ,,

Out of a total of 113 adult females only 7 were found to be engaged in work away from home bringing in a reasonable wage. These were all doing domestic work of one sort or another, either in private houses or in factories. Needless to say, many others of the remaining 106 worked in their own homes, taking on quite substantial domestic responsibilities; but, since there is no means of accurately assessing the value of this work, these have been disregarded.

Discussion

Since the great majority of ascertained mental defectives who subsequently have been shown to be employable are ascertained in school, it is clearly of the utmost importance to safeguard against any stigma such as was present under the classification required by the Education Act, 1921. Under the new Education Act it will be the duty of every local education authority to ascertain the children within their area requiring special educational treatment. The parent of the child may be required to present him for examination by a medical officer of the local education authority to determine whether he is suffering from any disability. It would appear that the child will hold a status of educational disability rather than acquire the label of a mental defective.

As regards the legal status of the adult, it would appear that he is either a certified mental defective or not, and, where he is an ascertained mental defective, presumably he has full legal capacity.

From study it has been found that those ascertained mental defectives in employment are conscientious and industrious, and in many cases use the money they earn to help maintain the household. The jobs at which they are employed are real and necessary contributions to our mode of life. They are not really misfits in the community; it is rather that in the normal peacetime labour market they are unable to get the jobs for which they are best suited. Kannar (1942) suggests that these persons should be described as of "intelctual inadequacy" rather than of mental deficiency. He points out that the mental defective in the true sense of the word has no place in the war effort of the United States of America, but that the majority of the "intellectually inadequate" can very well be integrated into the defence industries.

The Central Association for Mental Welfare, in its 21st annual report (1934), considers that ascertained mental defectives can only be supervised in the community so long as this is done by trained workers, and where facilities are available for occupation and training. From the findings of this study, however, it would appear that with favourable conditions some ascertained mental defectives can find and keep employment, when this is made available to them, without the intervention of trained social workers.

Possibly the position is overstated by Dayton and Nugent (1941) in claiming that institutionalization should be the last resort when all other efforts have been exhausted. Rather what is wanted is some system of assisting these persons to find suitable employment near their own homes, as was done years ago in New York City, where a bureau was established to place such persons in suitable gainful employment—see Davies and Williams (1930). In addition to this some financial aid should be provided by the State, as in the case of blind persons; this would indeed be cheaper than institutionalization, and might well be included in any comprehensive system of social security. Further, it has been said that institutional training tends to adapt the defective to the institution rather than to the outside community. Supervised life in the community and assistance to find suitable employment with financial aid in peacetime would train a greater number of ascertained mental defectives who are intellectually inadequate to adapt themselves to the environment of the community and to become responsible and useful citizens.

Summary and Conclusions

Out of a total of 227 ascertained adult mental defectives under supervision in Gloucestershire some 48 are now in full-time gainful employment.

Out of this total of 48 cases in employment 44 were ascertained in school. This emphasizes the importance of the status given to such children by the new Education Act, in which they are regarded as children with an educational disability.

For male defectives farm work is the most popular, and by reason of labour shortage they are now able to secure such employment.

In peacetime conditions, however, they will once more fall out of employment, and it is therefore suggested that they should receive assistance to find suitable jobs and, if necessary, financial aid in order that they may have the opportunity of fitting in with any comprehensive system of social security.

I am indebted to Dr. H. K. Cowan, county medical officer, for his help and for permission to publish the results of these investigations.

HOME AMBULANCE SERVICE

The Home Service Ambulance Committee of the Order of St. John and the British Red Cross Society in its twenty-fifth annual report recalls that the committee was set up in April, 1919, as an experimental measure, to provide a chain of ambulance stations throughout the country, primarily to serve the needs of rural areas. By October of that year 296 ambulances had been allotted and 171 delivered. To-day the total number of ambulance stations is 530—131 equipped by the committee and 399 affiliated stations. The report, though unavoidably delayed (it covers the year 1943), provides ample evidence of the value of the service to the scattered population of country areas. During the year 297,864 patients were carried, bringing the total number using the service since it started to 3,173,658. In an accompanying letter the committee's joint secretaries refer to comments that have been made on shortcomings in existing ambulance services. They point out that the Home Ambulance Service is administered throughout England and Wales on a county basis with headquarters in London, and the organization lends itself readily to any regional or national scheme.

"The service, free from red tape, is always ready to meet emergencies as they arise. No ill-judged rules or regulations as to areas or boundaries are permitted to delay the prompt aid that may mean the difference of life or death to the patient. In such a service the welfare of the sick and injured must be the first consideration. These ambulances work in a field where they are self-dependent, to a very large extent, for the preparations of the patients for safe transport. They must not only be equipped with first-aid materials and sick-room requisites, but must include staffs trained and qualified to deal with casualties and invalids under the most difficult conditions. It is for just such work that the training demanded by the Order of St. John and the British Red Cross Society equips their members. Duties are more or less evenly divided between the men and women of the divisions and detachments. The nurse escort is an aspect of the work which has been developed considerably in recent years, and with the return to normal the ambulance staffs of the Order and the Society will be available as a trained and sympathetic body of men and women ready to take their place in the National Health Service."

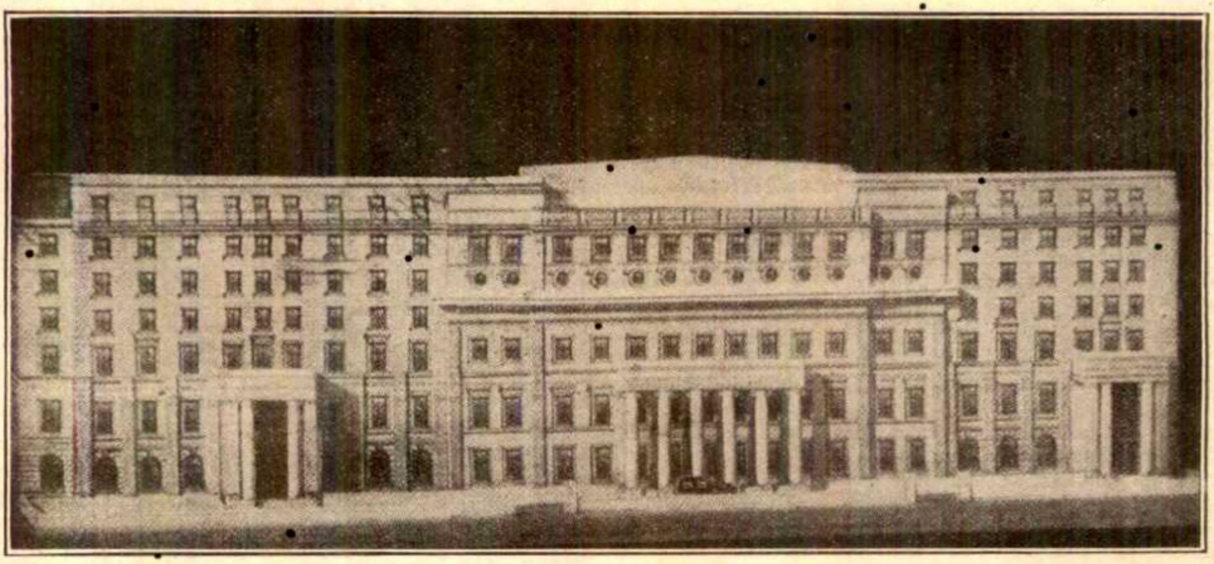
AWARDS TO CIVIL DEFENCE M.O.s

The *London Gazette* has announced the appointment as M.B.E. (Civil Division) of Dr. Una Mary Mulvany (Mrs. Swanston), medical officer in charge of first-aid post, Civil Defence Casualty Service, Southsea, and Dr. Tertius Thomas Bryce Wood, officer-in-charge of mobile unit, Civil Defence Casualty Service, Watford. The citations read as follows:

> Dr. Mulvany has been on duty during every heavy raid and has always been on her way to duty within seconds of the first bomb falling, never waiting to be called. By her unfailing courage and complete disregard of danger she has set a wonderful example, and her kindness and cheerfulness have given great comfort to many. On one occasion when a building received a direct hit Dr. Mulvany immediately went to the scene. She worked her way through the debris to reach three people who were trapped in the cellar and administered morphine to them. Although she must have known there was imminent danger of the place collapsing, she remained with them for nearly two hours.
>
> A flying bomb damaged houses and people were trapped. During the early stages of the rescue work walls were still collapsing and fires were burning. Dr. Wood took risks on many occasions in order to administer morphine to the injured trapped in the debris. His cheerful leadership and devoted service were an inspiration to the other rescue workers, and his efforts not only contributed materially to the saving of life but were a real source of encouragement to the trapped persons.

ORTHOPTIC TEACHING AND TRAINING

Orthoptic treatment has been on a scientific basis for ten to fifteen years. Formerly attempts to improve binocular vision were rather half-hearted and limited to the practice of a few progressive ophthalmic surgeons. Maddox devoted a great deal of time and energy to the subject, and, by his recognition of the difficulties and his systematization of treatment, may be regarded as the founder of the orthoptic treatment of to-day. The main object is to awaken a dormant or to stimulate a weakened desire for binocular vision. Undoubtedly there are cases where the mechanical difficulties presented by the alignment of the eyes, non-cooperation on the part of the patient, or the absence of any central area capable of response make all attempts to train binocular vision hopeless. Setting aside such cases, a large proportion of the remainder can be given full or nearly full binocular vision. The benefits to be derived from it, apart from the cosmetic effect, are such that the long and arduous training sometimes required is fully justified. The value of accurate depth perception, which accompanies full stereoscopic vision, is likely to be enhanced in the future when, it may be assumed, we shall take more and more to the air as a means of transit. Without depth perception judgment of distance is impaired and accurate landing of aircraft a hazardous proceeding. The work of the orthoptists attached to the R.A.F. may be cited as an indication of the importance of this field; by the use of orthoptics not only are men eliminated who are unlikely to be able to fly, but confidence is restored in those who, through stress and strain, find that flying is becoming difficult. Orthoptics is practised by medical auxiliaries who are certificated and registered. They are usually women, and before being trained they must give evidence of a certain educational standard. A course of about two years' training is followed by an examination consisting of written papers and practical work, the questions being set by ophthalmic surgeons and orthoptists, and the practical tests being carried out by orthoptists under the supervision of ophthalmic surgeons. On the results of this examination a certificate is granted by the Council of British Ophthalmologists. Orthoptists have to conform to a code of ethics agreed upon by the C.B.O., and everything is done to maintain the dignity of the profession. That the British Orthoptist Society is a live body is shown by its publication, the *British Orthoptic Journal*; the current number for 1944 contains many outstanding papers of interest to ophthalmic surgeons and orthoptists.



A COMMON COLLEGE SITE IN LONDON

Recent correspondence in the *Times* gives a fillip to a project which has been occupying many minds during the past two or three years. In essence the idea is to house the Royal College of Physicians of London, the Royal College of Surgeons of England, and the Royal College of Obstetricians and Gynaecologists on adjacent sites. It has been considered by the Standing Joint Committee of the Royal Colleges, which believes that common action of the three Colleges and closer relations could thereby be promoted. There can be very few to-day who would deny this as a general proposition.

The Lincoln's Inn Fields Site

The Royal College of Surgeons now owns the freehold of Nos. 35 to 45, Lincoln's Inn Fields—a site approximately twice as large as that occupied by the College buildings before the war. It also owns two other houses on the south side of the square, though these do not quite adjoin the main site. The Council of the R.C.S. favours the development of this site as the home of the College, while adhering to its view that to achieve joint buildings is more important than any considerations of geographical position. In its last annual report (1944) it reaffirms its willingness to consider any proposal for moving elsewhere, but feels that the Lincoln's Inn Fields site has great advantages, and that these should be most seriously considered and not lightly rejected. It must be satisfied that removal from the present site would have overwhelming advantages, for it regards Lincoln's Inn Fields as being a satisfactory situation for the numerous activities of the College and as being known throughout the world as the home of the Hunterian Museum. It is, however, prepared to make big sacrifices if convinced that a move is necessary or advisable for the promotion of better relations and facilities between the three Royal Colleges.

In short, the Council of the R.C.S. would like Lincoln's Inn Fields to be the site of a common Collegiate Centre because of its favourable circumstances and amenities and its accessible position, and earnestly hopes that this view will prevail. But it is a matter of great urgency for the R.C.S. that a decision should be made. The part of the College still intact is being put into working order to provide for the impending return of the research laboratories and to give accommodation for the new professor of human and comparative pathology. There is also a pressing demand for facilities for the restoration of museum specimens, the repair of material from dispersed centres, and the care of such new material as is reaching the College. The damaged museum halls will soon have to be put into commission to house new specimens promised from all parts of the world and to accommodate the 27,000 specimens now stored in this country. In addition to parts of the College only needing restoration there remain the parts of the original site which were occupied by buildings completely destroyed by enemy action in May, 1941. This space is now available for reorganization, and can be planned to give accommodation both for common use by all the Colleg and for the specific use of each. The R.C.S. is also prepare to arrange its rehabilitation so as to put to joint use existin or restored facilities, such as museums, laboratories, an libraries.

To give some idea of how combined buildings might b laid out on the site a ground-plan has been prepared for th R.C.S., and also a design of a suggested façade (reproduced o this page). The architectural plans were drawn with the ide of showing one of the possible ways by which the require accommodation could be provided. It is the hope of th Council of the R.C.S. that the other Royal Colleges in Londo may agree to move to Lincoln's Inn Fields and combine i forming a medical centre.

The greater the age of an academic body the harder become its decision in a matter of this kind. The Royal College o Physicians of London—by far the oldest medical college i this country, for it was founded by Henry VIII in 1518—ha moved house three times during its long history, and th Fellows are naturally and properly concerned lest in an further move it may lose something of its autonomy and it prestige. But there is much to be said for a collegiate medica centre in London and for physical juxtaposition. Those wh take the long and the wide view will welcome the genera conception of a joint site and be glad that it is now unde discussion in the public press; they will be encouraged b knowing that Lord Dawson, who was for seven years Presiden of the R.C.P., has announced himself in favour of the pla subject to all necessary precautions.

The Present R.C.P. Building

Sir Stewart Duke-Elder reopened the whole matter in th *Times* on Jan. 10 with a letter which linked the question o a central site with his earlier advocacy of a comprehensiv Academy of Medicine in London. Lord Dawson, writing i the next day's issue, gave his blessing to the general idea an added some important facts about the Royal College of Phys cians and its present site which will be news to most reade and even to many Fellows of that College. Before 1930 th R.C.P. unanimously decided, after expert advice, that its building in Pall Mall East at the corner of Trafalgar Square wa unsuited for its purpose and that a new home should be sough At that time the Canadian Government was seeking to enlarg its Dominion offices, and for this purpose desired to buy th adjacent R.C.P. building. By 1934 negotiations for the sale o the College site were nearly complete, when a change o Government in Canada stopped the negotiations, though th new Canadian Prime Minister and High Commissioner retaine their active wish to secure the R.C.P. site for an addition t Canada House. Lord Dawson recalls that the Joint Committee of the three Royal Colleges, which was formed i January, 1942, decided unanimously that the securing of single site for the Colleges was of more importance than th qualities of any particular site. "But the war seemed t obstruct any such scheme until by a fortunate turn the Royal College of Surgeons saw the opportunity for a bold initiative and seized it. . . . It is a rare opportunity for the realization of a great idea and does credit to the man who conceived it. The present Canadian Government is still wishful, subject to negotiation, to purchase the R.C.P. building, and it has made this fact known to the President of the Royal College of Physicians, with the wish for its general knowledge. Surely the unrivalled opportunity offered by this Lincoln's Inn Fields site should be studied carefully."

Reports of Societies

B. COLI PYELITIS: DIAGNOSIS AND TREATMENT

At a meeting of the Section of Surgery of the Royal Society of Medicine on Jan. 3 the subject of discussion was "The Diagnosis and Treatment of *B. coli* Pyelitis." Sir JAMES WALTON presided.

Pyelitis in Infancy

Dr. WILFRED SHELDON said that pyelitis might be met with in children's hospitals even in the first week of life. It was most common in childhood in the first year. Not infrequently it arose as a secondary disease, and the most common predisposing influence was gastro-enteritis. In young children also it might arise as a complication of acute otitis media or pneumonia. He did not think he had ever seen a very severe case of infantile scurvy that had not also got pyelitis. In primary cases the temperature rose 4 or 5°, and there was a day's swing of perhaps 3 or 4°. In young children there might be convulsions and rigors; vomiting almost invariably occurred. In young children restlessness and irritability were very marked; in older children irritability was likely to be replaced by headache and pain in the loins. Pain was not a prominent symptom, but in some cases there might be severe attacks. Errors of diagnosis would continue to be made so long as the routine examination of the urine was omitted from the clinical examination.

Before the appearance of the sulphonamides, acute *B. coli* pyelitis was treated with alkalis, usually with conspicuous success. The sulphonamides were such efficient sterilizers of the urine that they would often exert their effect in the presence of urinary stasis. In acute pyelitis, when there was no opportunity of indicating whether urinary stasis was present or not, if these drugs were used as a first line of attack they should be followed by routine pyelography lest some underlying cause was being overlooked. It was his practice to continue to treat these children by means of alkalis, and, if these failed, then to go on to sulphonamides, and later to investigate this particular group by pyelography. Among the sulphonamides his personal preference was for sulphathiazole, and the amount aimed at was 0.2 g. per kilo per day. He gave a small dose of alkali with each dose of sulphonamide to assist toleration. *B. coli* was in the group of organisms insensitive to penicillin, and therefore its use was not likely to be beneficial.

Pyelitis in Adults

Mr. E. W. RICHES said that two main clinical varieties must be recognized—namely, acute or subacute, and recurrent. So-called chronic pyelitis was always a pyelonephritis with tubular involvement, and often the name "recurrent pyelitis" concealed some other lesion which was responsible for stasis continuing. Two principal aetiological factors were concerned in acute pyelitis: (1) lowered resistance, and (2) bacterial invasion. Lowered resistance was often exemplified by a chill before the attack started. Bacterial invasion was generally from the bowel; constipation or diarrhoea gave the clue to its origin, and the infection was usually lymph-borne from the colon. The distinction between pyelitis and cystitis was somewhat arbitrary. If pyrexia or renal pain occurred with cystitis the label "pyelitis" was attached. The symptoms in the acute phase were pyrexia, renal ache, polyuria, frequency, and diarrhoea, and sometimes painful haematuria. The urine was characteristically acid, pale, of low specific gravity, with an unpleasant odour, and a surface sheen which developed on standing. Response to medical treatment was evidence of the correctness of the diagnosis.

Treatment of the acute case was rest in bed, warmth, copious fluid intake, attention to the bowels, and alkalis in large enough doses to make the urine alkaline. When the temperature had been normal for some days the continued presence of *B. coli* or pus demanded a course of either one of the sulphonamides or mandelic acid. The sulphonamides were more rapid in their sterilizing effect. They acted in about half the time taken by the mandelates. The drugs were not always well tolerated, and might give rise to nausea and vomiting. Efficiency and toleration seemed to be best combined in the use of sulphadiazine. For a pure *B. coli* infection he found mandelic acid more generally useful than the sulphonamides, though it also was unpleasant to take. It could safely be ordered for an ambulant patient. For the speediest cure sulphonamides should be given with alkalis from the outset.

In the diagnosis of the recurrent or persistent case, the trauma or other cause keeping up the infection might lie in the urinary tract itself, or in the genital or intestinal tract. As the lesion was most commonly found in the urinary tract investigation should, as a rule, start there, and the most useful starting-point was an intravenous pyelogram. He preferred to do this before cystoscopy. Any lower urinary tract obstruction would be discovered on cystoscopy, if not before, and any lesion in the bladder, such as new growth, diverticulum, or stone, would be found. Retrograde pyelography was carried out at the same time if the previous excretion pyelogram indicated the need for so doing.

Uncomplicated acute pyelitis due to *B. coli* would respond to medical measures. Instrumentation played little part in its treatment. The effective urinary antiseptics were mandelic acid and sulphonamides. A patient who did not respond to a properly given and supervised course of treatment should be regarded as having some other lesion. The persistence of pus cells after the urine had been sterilized was a warning that recurrence of infection was likely.

Pyelitis associated with Child-bearing

Mr. DOUGLAS MACLEOD said that some degree of pyelitis occurred in about 1% of all pregnant women. This was undoubtedly due to certain physiological conditions in pregnancy, especially the marked atony of the ureteral muscle, which had been shown to occur as early as the eighth or tenth week. The effect of compression, especially on the right ureter, had to be reckoned with; in a pyelogram taken at the twenty-fourth week the right ureter would in most normal pregnancies be seen to be much dilated, and this dilatation affected the calices and ceased abruptly at the pelvic brim. The ureter was also kinked in the middle and upper thirds. Dilatation due to atony occurring early in pregnancy affected the left ureter equally with the right; dilatation due to compression affected, as a rule, the right ureter. The cause of the muscular atony was thought to be the presence of a hormone with an inhibitory influence on all plain muscle. In diagnosing pyelitis in pregnancy the difficulty was its occasional confusion with appendicitis. An outstanding symptom might be extremely severe vomiting. With regard to treatment, many obstetricians preferred sulphanilamide; he himself used sulphathiazole and sulphadiazine, though there was a danger of the drug crystallizing out in the tubules. Infections in the puerperium were common and were treated with sulphanilamide. This was excreted in the milk, but did not seem to cause any harm. Finally, he pointed out that although mild cases of pyelitis were common in pregnancy, and often overlooked, the acute severe form was rare. At Queen Charlotte's, out of 1,500 deliveries in a recent year, there were only six cases.

A Pathologist's View

Dr. HOWARD HUGHES said that there was a minute but rapidly growing group of cases in which all forms of therapy seemed to fail. The general practitioner had given courses of a sulphonamide, alkaline mixtures, and so forth, and had finally sent the case to a surgeon or physician, by which time either the micro-organism or the patient was unsuitable for any further chemotherapy. Here the laboratory could help by adding something to a case in which it was known that the patient had already had treatment for some time. The pathologist could say whether a particular strain found was sensitive or not to the favoured drug of the physician with whom he was co-operating. There was no difficulty in adding the *in vitro* information. He added that in *B. coli* pyelitis a mixed group of related organisms were concerned which were not antigenically all the same.

Mr. WINSBURY WHITE said that it was the recurrent cases into which they wanted to probe.

A man of 35 was sent to him some months ago with the history that he had had an attack of cystitis and pyelitis, with *B. coli* found, but that this had cleared up, leaving him with chronic frequency and pain at the end of passing water. The pain was very worrying, and the practitioner wanted to know whether the man had stone in his bladder. The patient said that for years preceding his attack he had bouts of frequency of micturition. On examination a number of tags of inflammatory tissue were found in the posterior urethra. He saw the patient three weeks afterwards, and then his frequency was much reduced and his dysuria had disappeared completely. The bouts of frequency suggested a focus of infection somewhere near the neck of the bladder; fluctuating in intensity from time to time until eventually one of the bouts went further and caused cystitis and an attack of pyelitis.

It seemed to him that some of these cases settled into chronic pyelitis. In the female often everything appeared normal except for a patch of inflammation in front of the trigone. The urethroscope showed invariably chronic inflammation there as well, and it was quite common for early cases to clear up merely as a result of the instrumentation, though this must not be expected in severe cases.

Route of Infection

Mr. JENNINGS MARSHALL asked where was the source of infection and how did the infection reach the urinary apparatus. It could arrive either by the lymphatics or by the blood stream. The *B. coli* group of organisms could be excreted by the kidneys alone, and therefore a blood-stream route need not surprise them. The source of the coliform group must be the bowel at some point. For years people had talked about the passage of these organisms through the intact bowel wall, but was there any part of the bowel which was constantly being lacerated? There was such a part in the anal canal, which was very subject to laceration, as, for example, when affected by piles or by cryptitis. On the top of these frequent lacerations was the important factor of muscular spasm. Here, then, was a means of the infection getting into the system, whether by the blood stream or by the lymphatics.

Mr. KENNETH HERITAGE considered that the value of alkalization of the urine ought not to be forgotten with the advent of the sulphonamides. Alkalis had given patients great symptomatic relief when sulphonamides had failed. He also referred to the pyelitis which occasionally followed the use of instruments in urology. Do what they would they could not always avoid this complication. Instrumentation might render patients more prone to fall a prey to their bacteriaemia. He emphasized the value of the prophylactic use of sulphonamides as a means of preventing post-instrumentation rigor.

Mr. HAROLD DODD declared himself a rebel in that he believed in intensive acidification, giving acid in the same way as alkalis were given. In his experience this worked well; he put it forward not as a routine treatment but as something worth trying. The daily intake of fluid played a big part in this condition, and the measurement of the fluid was as important as the measurement of the quantity of drug the patient was given. All milk should be boiled: there was no reason why the patient, having to grapple with his own bacteria, should have to grapple also with those of the cow.

Analysis of Cases

Dr. H. G. HANLEY presented an analysis of 200 cases of *B. coli* pyelitis in women of child-bearing age—100 consecutive cases in pregnant women and 100 consecutive cases in non-pregnant:

	100 Non-pregnant	100 Pregnant
Congenital lesions	5	5
Calculi	5	6
Hydronephrosis	6	4
Tuberculosis	2	1
Gross genito-urinary pathology	18	16
Previous genito-urinary infection	32	37
Known previous pathology before this attack	46	50
Defloration ("honeymoon pyelitis")	7	—
Urethrotrigonitis	44	(in 16 out of 47 examined) 37
Cases with a possible primary causal factor	69	54

The difference between pregnant and non-pregnant women was insufficient to allow pyelitis of pregnancy to be classed as a disease on its own. Pyelitis was rarely an infection of the kidney; it was usually an infection of the genito-urinary tract. He commented on the decrease in the number of cases of pyelitis in the war years.

The PRESIDENT (Sir James Walton) said that it seemed to him that evidence was accumulating that throughout the body an ascending infection rarely if ever occurred. The infection under discussion seemed to be much more of a septicaemia—a blood-borne infection. He asked what was the ultimate prognosis. What happened in the case of young girls who early in life had been treated for "pyelitis"? Mr. RICHES replied that many young girls who had had pyelitis in their early years had grown up and passed successfully through pregnancy. He did not think it could be held now that "once a *B. coli* pyelitis always a *B. coli* pyelitis."

SOVIET SURGERY

Meeting of Anglo-Soviet Medical Council

The Anglo-Soviet Medical Council continues with unabated zeal its work of bringing the medical professions of this country and the U.S.S.R. into closer contact, chiefly by facilitating the interchange of information on professional matters. Among its activities is the publication of a monthly news sheet entitled *Soviet Medical Chronicle*. With the medical professions of both countries so heavily engaged in caring for the sick and the wounded on the many fronts of war, free communication between them must obviously be limited. The success of the work of the Anglo-Soviet Medical Council is in large part due to the untiring patience of its honorary secretary, Dr. Elizabeth Bunbury, who gave an account of her stewardship at the third annual general meeting of the Council recently held at the Royal Society of Medicine, when the President of the Council, Sir Alfred Webb-Johnson, was in the chair. After the ordinary business of the meeting had been completed, Sir Alfred welcomed Prof. N. N. Priorov, Director of the Central Institute of Orthopaedics and Traumatology of the U.S.S.R., and Dr. A. Kotov, Assistant Director of the Ukrainian Institute of Orthopaedics and Traumatology. A translation of Prof. Priorov's address on Soviet surgery was then read by Dr. Charles Wilcocks.

Soviet surgery, Prof. Priorov said, had been able to return to the fighting Services as many as 70% of the casualties. At the front their aim was to provide surgical treatment as close to the front line as possible, and to arrange a high degree of specialization of treatment during the first few hours in the field hospital, with a thorough surgical classification of the wounded according to the nature and type of injury. After classification, the wounded were evacuated to specialized hospitals. The hospital organization comprised a network of specialist hospitals, large surgical departments in all general hospitals, and the 50 medical institutes in the different republics and regions of the Union. Each institute had three chairs of surgery, occupied by a professor specializing in one or more subjects. There were also special central institutes such as the Central Neurological Institute, the Central Institute of Blood Transfusion, the Central Institute of Orthopaedics and Traumatology, and the Central Tuberculosis Institute. These institutes carried out research and served as centres of information for peripheral institutes. The Commissariat of Health had formed a Scientific Council to act as a clearing-house to co-ordinate research work and to make the advances known to the medical profession. Each year this Scientific Council had submitted to it scientific work done by the large hospitals, clinics, and institutes, and the research problems indicated by them and by the People's Commissariat of Health. There were also a Hospital Council at the Commissariat of Health, and a Scientific Council of the Medical Administration of the Red Army. An Academy of Medical Sciences had just been established.

Much work had been done on the bacteriology and chemistry of wounds. Tens of thousands of wounded had had secondary suture performed 8, 10, 12, or even 20 days after injury, with satisfactory results. Sulphonamides, and recently penicillin, had been used extensively. In the treatment of fractures the apposition of the bone fragments was considered as urgent as operation on a strangulated hernia. The problem of osteomyelitis after gunshot wounds was far from being solved; mere sequestrotomy or curettage was insufficient; transverse or lateral resection of the affected part should be carried out. In the treatment of injury of the peripheral nerves they did not favour transplantation when there were defects of nerves and the ends could not be approximated: they advocated plastic operations on the muscles, and suitable orthopaedic devices. A number of orthopaedic operations were performed in the network of hospitals established for surgical rehabilitation. The percentage of amputations had been diminished by half, as compared with the war of 1914–18. Prof. Priorov mentioned the case of a doctor who had lost both arms, one above and the other below the elbow: after being supplied with artificial limbs capable of movement, he was able to look after himself, use a typewriter, and perform the duties of a public health inspector. He concluded by expressing a hope for still closer contact and a fuller exchange of views and experience between the medical professions of the U.S.S.R. and Great Britain.

Correspondence

In Aid of Russian Wounded

SIR,—The Joint Committee for Soviet Aid has been granted official permission to hold a flag day in the Greater London area on Red Army Day, Feb. 23, which will mark the 27th anniversary of the foundation of the army of our Russian allies who during this winter have faced more than 220 German divisions on the Soviet-German front.

To rehabilitate hundreds of thousands of wounded is one of the new tasks facing Soviet surgeons. If all the equipment, apparatus, and special hospitals needed for this can be established:

35% of the war invalids can be completely rehabilitated and ultimately return to the ranks of the Red Army.

30% of these invalids can return to their previous civilian occupations.

Others can, after special training and re-education, be employed in various suitable occupations instead of feeling themselves unable to play their full part in the life of the community.

The proceeds of this flag day will go to help provide rehabilitation equipment for the Red Army wounded. As flag days are also being held very widely throughout the Provinces may I appeal to all members of the medical and nursing professions to give every support possible during Red Army Week and on the flag day itself.—I am, etc.,

P. CHALMERS MITCHELL,
Hon. Treasurer.

Joint Committee for Soviet Aid,
171, St. Stephen's House, Westminster, S.W.1.

Relation of Neurology to Psychiatry

SIR,—Dr. Shepley (Dec. 23, p. 833) writes of the "total absence of demonstrable organic lesions such as are constantly sought but rarely found concomitant with gross examples of mentally disordered states." This statement is incorrect, for in my experience organic lesions of the cerebral vessels are generally demonstrable in brains from mentally disordered patients. Neuron lesions may also be found, especially where neurological signs have been present, although they do not affect the problem, as I have pointed out that clinical recoveries, remissions, and lucid intervals obtaining after many years' mental illness establish the integrity of that part of the nervous system subserving the recoverable mental function. The mechanism at fault is that which governs neuron stimulation thresholds, thus determining the paths of sensory impulses through reflex arcs to give desired responses—namely, the pattern of blood flow in the cerebral capillaries—and the "recent notable advances (as well as the older methods) in psychiatry in treatment by physiotherapeutic methods" all depend upon changing local cerebral blood flow.—I am, etc.,

Birmingham. F. A. PICKWORTH.

Nursing of Tuberculosis

SIR,—The letters of Dr. Snell (Dec. 9, p. 768) and Dr. Wingfield (Dec. 30, p. 867) following your annotation on the nursing of tuberculosis call for comment. As a result, we suppose, of two misprints little can be said about the figures in Dr. Snell's letter; but when those he quotes from the Prophit Survey report by Daniels are corrected they remain misleading. He says that in the Mantoux-negative group of that survey (452 not 42) 33 developed tuberculosis. In fact there were 12 cases of clinically active pulmonary tuberculosis and 1 of non-pulmonary tuberculosis. The remaining 20 were primary manifestations, including 6 pleural effusions. The recommendation made by Daniels is that tuberculin-negative nurses should not nurse in the tuberculosis wards of *general hospitals.*

Dr. Wingfield appeals for wide publicity of the dangers of nursing tuberculosis. We feel that narrow publicity among those responsible for the health of hospital staffs would be more useful and less likely to diminish even further the number of entrants to tuberculosis nursing. The burden of the American paper he quotes is a plea for a better scheme of health control for hospital workers.

Now that the habit of repeated tuberculin testing and radiological examination is spreading, primary tuberculous infection is increasingly often recognized. And as primary tuberculosis is normally a benign condition, even in the young adult, it is high time that the difference between primary tuberculosis and progressive pulmonary tuberculosis—phthisis, if you like—was generally and officially recognized. This differentiation has been advocated in a recent editorial in *Tubercle*, and in a scheme of classification devised by Houghton.

In the present state of tuberculous infection in this country virtually all the girls who are Mantoux-negative when they start nursing would become Mantoux-positive within the next ten years, whether or not they nursed tuberculosis. We believe that a sanatorium is as good a place as any other in which to acquire tuberculin sensitivity. A paper on the subject is in preparation by us, but our reasons for this belief may be stated briefly.

1. There may be something in the theory that a massive infecting dose is dangerous. This is less likely to be received from well-trained patients in open-air conditions with a known risk and consequent precautions than from the unsuspected case in the ill-ventilated ward of a general hospital.
2. A well-planned scheme of staff health control should ensure the early recognition of primary infection, and the necessary steps can be taken to prevent the development of progressive pulmonary tuberculosis.
3. The general health and physical condition of the sanatorium nurse are commonly better than those of her opposite number in a general hospital.

Finally, may we deal with a purely practical point. Approximately 25% of our student nurses are Mantoux-negative on entry, so if we excluded these we would only have to close down about a fifth of our beds. When the age of infection is postponed as late as it is in some parts of America, we might have to turn down 84% of applicants. What happens then?—We are, etc.,

PETER W. EDWARDS.
Cheshire Joint Sanatorium, Market Drayton. A. CLARK PENMAN.

Prisoner-of-War Mentality

SIR,—I have been interested in the correspondence on the prisoner-of-war mentality. At the beginning I was tempted to write and suggest that the psychological treatment necessary would be more valuable if directed to the wives and families of returned prisoners-of-war in teaching us the necessary attitude which must be adopted by those of us who have been waiting with varying degrees of impatience for their ultimate return.

Major Charters's letter (Jan. 6, p. 24) is of great comfort to me, as I have had anxiety about a neurosis engendered by enforced idleness, and it may be of interest to others to know that I have just received a letter, the first for three years —one hundred words in capital letters—from my husband, who is in Japanese hands. He says: "I am in good health but very weary of this kind of existence. *Fortunately* there is plenty of work to do and mind is kept fully occupied." I make the emphasis as I think it reveals my husband's desire to dispel what he knew would worry me most about his own case.

He is a psychiatrist in the R.A.F., and I feel that the problems of incarceration will be adequately dealt with so far as he is able to organize activity in his own camp (Osaka). There must be other doctors who are aware of the dangers and doing yeoman service in the camps.—I am, etc.,

I. MAGRATH.

Aggressive Impulses in Progressive Society

SIR,—In recent work carried out among the neurotic, and to a lesser extent among the psychotic, the delinquent, and the criminal, there is some evidence to think that the primary stimulus in all individual breakdowns is to be found in the environment in early life, and that such stimulus is invariably associated with exploitation in some shape or form which had generated a store of infantile hate so primitive as to be quite unpermissible to the developing adult; it has had to be locked away in the psyche and has constituted a danger to the individual, for he has become more vulnerable to such a type of stimulus later in life. The factor of exploitation is also to be reckoned with where a breakdown occurs in social or international relationships.

A confirmation of this is to be found in a book published in 1934 by an American psychiatrist, Dr. F. E. Williams, entitled *Soviet Russia Fights Neurosis*. The author gave his views on what was wrong with the world, and what preventive measures might be adopted which would lessen unhappiness in general and the incidence of neuroses and psychoses in particular. He had much praise for the Russian realistic approach to this subject, and contrasted their methods favourably with those of America. He said that the Russians recognized the importance of environmental factors for the happiness of every citizen or group of citizens. He pointed out with what success they had organized a society where the normal aggressive impulses bound up with growth and expansion were allowed to flourish so far as possible without interference, so freeing the constructive impulses without the inhibiting infiltration of hate—an effort towards a preventive form of therapy.

He regarded exploitation, however subtly applied, and the guilt and hate generated thereby, as largely responsible for individual and social unrest, and warned his readers of what would happen if world affairs were allowed to continue to drift. His prophetic words of 1934 passed unheeded at that time, but may well be re-read in the light of subsequent world happenings, especially now that some of our own psychiatrists have to a large extent confirmed his findings, and as there is now a need to plan for a future peace. The book asserts that for a realistic basis of life man must accept and trust his own tendency towards aggression: "We must be free to be aggressive; the question is how to manage this aggression and how to turn it to social account. Man must learn to use his aggression in a constructive, positive way." Energy bound up with the free liberation of aggressive impulse lies behind all progressive growth, whether of child, adult, or State.

In the light of such evidence, were we to search for a satisfactory world ideology it might be found to be worth while to remember to imitate Russia in this respect: to make an effort to purge our social life of old worn-out pre-war conceptions based so largely on exploitation of the less well-informed by the better-informed; to do away with a secular system that encourages one section of the community or one nation to batten upon and exploit another, and a religious system that hoodwinks the unintelligent and postulates that the dead can exploit the living; and instead to attempt to build an ideology based upon mutual service rather than on mutual exploitation, and found a society less influenced by "fear of the dark." Society would be all the better if it could become completely adult, freed from fears, bogies, and superstitions associated with infancy, which have hitherto through the ages dogged its footsteps. Only then shall we be able to live an adult life along reality lines, guided by a religion that preaches happiness in this world, and not unhappiness here as a necessary preliminary to a problematical happiness in a problematical next world.—I am, etc.,

London. A. CYRIL WILSON.

Artificial Insemination

SIR,—The child born as a result of extramarital artificial insemination is an illegitimate child, and has no right of succession; moreover, if the child is registered as the offspring of a married couple, when in fact it is only the child of one of them, the law of the land is broken, and the doctor who performs the operation of artificial insemination is surely an accessory to the misdemeanour.

If it is desirable for the wife in a childless marriage to have a child as the result of artificial insemination is it not theoretically just as desirable that the husband in a similar marriage should have a child by another woman, and by a false declaration declare that the baby is the child of himself and his wife? The view of the courts on this aspect of the problem was demonstrated not so long ago, when a doctor was charged with having registered two children as the offspring of his wife and himself, although in reality they were his children by another woman; for this offence he was committed to prison and his name removed from the *Medical Register* by the General Medical Council.

It has been maintained in this correspondence that adoption of children is not the answer to all childless marriages, but in the course of what is now a fairly long experience in paediatrics I have found that such a procedure has almost always been a pronounced success. The few failures have been in those instances in which some time after adoption the child was found to be suffering from some congenital disease or was a weakly child—failures which can usually be guarded against and which do not justify recourse to artificial insemination. The success has not even been diminished in those not rare instances in which, after having adopted a child, the mother and father produce one of their own.

Many of your correspondents appear to think that the Church, and particularly the Roman Catholic branch of it, should not have any say on this subject, but matters concerning personal conduct, the sanctity of the home, and the married state are vital concerns of the Church. Nevertheless, whatever the Church as a whole may or may not say on this subject, it seems quite clear that those "who profess and call themselves Christians" can have no part in the practice of extramarital artificial insemination.

Apart, however, from the Christian standpoint on this subject, those who argue in its favour indicate thereby that in their view the father has no responsibility for training and care of the child which he has helped to create, and that his sole role in the business is that of a more or less wholesale provider of semen. Surely such an attitude is indefensible, since both mother and father should bear an equal responsibility for the life which together they have launched upon the world, and it is clearly the duty of doctors to impress this fact upon potential parents.—I am, etc.,

Birmingham. LEONARD G. PARSONS.

SIR,—In this discussion the relation between artificial insemination and masturbation has been dealt with, and obviously other sexual aberrations, such as sodomy, are not ungermane to the subject. Since you published a letter from me in your issue of Dec. 9 I have had an opportunity to read Dr. Julian Huxley's volume, *The Uniqueness of Man* (Chatto and Windus, 1941). This eminent zoologist emphasizes from the beginning of his work that the individual exists not for himself but for society. "If civilization," he says, "is to re-create itself after the war, it can only do so on the basis of what, for want of a better word, we must call a social outlook. . . . To the biologist, who is not afraid of being a humanist as well, *the essence of human life* is seen in *social* relationships" (my italics). In his first chapter, "Eugenics and Society," Dr. Huxley stresses the value for eugenic experiment of separating "the individual side of sex and reproduction from the social side"; otherwise of separating "sex from reproduction," nay, of separating "love" from reproduction. "The perfection of birth-control technique," he says, "has made the separation more effective; and the still more recent technique of artificial insemination has opened up new horizons, by making it possible to provide different objects for the two functions. It is now open to man and woman to consummate the sexual function with those they love, but to fulfil the reproductive function with those whom on perhaps quite other grounds they admire." Dr. Huxley proceeds even further, and maintains that "unless we alter the social framework of law and idea so as to make possible the divorce between sex and reproduction, or, if you prefer it, between the individual and the social sides of our sexual function, our efforts at evolutionary improvement will remain mere tinkering, no more deserving the proud title of eugenics than does the mending of saucepans deserve to be called engineering." From these quotations it would appear that this writer, in removing what he calls "love" from the social field does not consider it as belonging to "the essence of human life."

It has always, I think, and everywhere, until these latter days, been held that man's two essential functions were self-maintenance and race-maintenance, and that the sex functions existed for the latter purpose. Even the aesthetic paederasts of Ancient Greece and Rome would hardly have claimed that their sensual indulgences subserved "eugenic" ends. It would be valuable if readers having a better acquaintance than I with Dr. Huxley's writings would explain what he means by "love" in this connexion, since on that would seem to hang most of his argument.

To not a few of us the process of analysis *à outrance* which characterizes modern science, particularly biological and sociological science, seems to have played, and to be playing, a major part in that break-up of Western civilization which we now see at its climax all around—I mean, in the present war.—I am, etc.,

North Queensferry, Fife. A. J. BROCK.

Breathing and Coronary Circulation

SIR,—Dr. R. H. Dixon (Jan. 6, p. 27) will find breathing and the coronary circulation fully discussed in *Chronic Maladies*, a book by Dr. Todd of Bristol. Ten years ago, at 57, I found myself unable to walk even on the level without retrosternal pain and discomfort—an obvious candidate for coronary thrombosis. By following Dr. Todd's suggestions on breathing I can now climb almost any hill provided I do not go too fast. My chest expansion has increased from one inch to over three.

The coronary circulation depends on the efficiency of the pulmonary pump, and that on thoracic movement. Not for nothing is coronary thrombosis termed the "surgeon's disease." Half his working day the surgeon spends standing in a vitiated atmosphere, and "holding his breath" at that, and the rest in his car inhaling cigarettes; chest expansion, half an inch!—I am, etc.,

"F.R.C.S."

"Clausen's Harness": A Disclaimer

SIR,—Occasional references in your columns and elsewhere to "Clausen's harness" prompt me to point out that, though some years ago I did describe a mask-retaining apparatus, I can hardly claim authorship of the article as now sold. The flat "lifeless" rubber, the fabric inserts which destroy elasticity in the straps, the widely spaced holes which make adjustment difficult, the sharply recurved hooks which hinder application and removal—these are "improvements" for which I claim no credit.

In view of the inventive proclivities of anaesthetists it is perhaps surprising, as well as gratifying, that the article has survived so little changed—a proof of its usefulness if not of its perfection. But a protest against its too routine use may not be out of place, for it has its dangers. I would, in fact, like to emphasize the point made to me not long ago by a teacher of anaesthetics, that the student and the beginner should not be permitted to use any harness until they have mastered the art of holding the mask and the jaw by hand.

"Débridement" is hardly my affair, but words and their usage interest me. My *Larousse* tells me that the word means the act of removing the bridle from a horse, but if surgeons choose to use it with quite another meaning that is their affair, and does no harm so long as the implied meaning is agreed by all. "Tourniquet" may be such another adopted word, for *Larousse* gives many meanings for it in French, none of which has any surgical implications.—I am, etc.,

London, N.W.8. R. J. CLAUSEN.

The Future of the G.P. Surgeon

SIR,—May I be spared a little space to ventilate a point which is exercising many G.P. surgeons at present. In the spate of correspondence in the *Journal* since the Questionary I have not seen any discussion of the future of the G.P. who at present does surgery in cottage hospitals. It would appear that a doctor must in future be either a physician only or a surgeon of consultant standard. There must be many men who, by reason of long experience, have been acknowledged as surgeons, and many who, having a surgical degree, enter general practice with the justified intention of doing their own surgery. In a future extension of the hospitals it would surely be reasonable that these men could be used to great advantage, if only as juniors to consultants. No reasonable man would give them *carte blanche* in every field of surgery, but there is a definite place in which they would be quite at home. By reason of the close contact of G.P., patient, and local hospital the results of G.P. surgery compare very well with those of major hospitals in both "cold" and emergency operations. The latter in particular benefit by the time factor alone.

In this, as in many of the discussions of late, we feel very much in the dark, and any views or light on the subject would be appreciated. It is inconceivable that the large number of men who have spent time and money to cultivate an interest and degree of surgical skill should have to abandon their "specialty" and revert to the non-operating doctor role.—I am, etc.,

Crewe. J. K. B. WADDINGTON.

The Younger Men

SIR,—It is instructive to read two letters in the *Journal* of Jan. 6 (p. 28). "B.1," who is able to continue his studies during the most receptive period of life and enter for the higher examinations, asks for further economic and marital amenities. "Serving Officer," who may have been allowed six or at most twelve months' resident hospital appointments, has had no such opportunities, nor has he an equal chance to state his case. Under these circumstances the E.M.S. man has an enormous pull over his colleague on active service, and a far greater opportunity of entering the consultant or specialist ranks.

Observation of more than thirty hospital residents who have worked under me during the last six years has not made it apparent that those who enlisted were less promising material than those who obtained further deferment. This is unlikely to be an isolated experience. In common fairness a doctor who has suffered the hardships of active war service is entitled to at least as good a chance as his contemporary who has enjoyed less rigorous work. The assurance that young serving officers would be replaced by E.M.S. men at the earliest opportunity would relieve the discontent so many of the former feel. Both the future of medicine and eugenic considerations suggest the need for such a step.—I am, etc.,

New Milton, Hants. A. BASIL ROOKE.

Demobilization and the E.M.S.

SIR,—While sympathizing with many of the points raised in the letter by Majors Armstrong and Maddocks (Dec. 30, p. 869) I feel that they were unduly biased in their inability to "see one single reason why civil service should count."

The majority of us in the E.M.S. have been directed and kept there by the same controlling body which is also responsible for supplying the medical personnel of the armed Forces —the Central Medical War Committee. In my own case, on volunteering for the Navy at the outbreak of war I was turned down, being "too old at 35." Hoping to become more useful and to ensure some clinical work when the inevitable call-up came, I acquired a diploma in anaesthetics, and again volunteered. This time I was told that no more anaesthetists were needed because of the comparatively few casualties at that time, and was strongly advised to join the E.M.S. For three and a half years I have worked whole-time in the same hospital. Undoubtedly I should have been replaced if the Central Medical War Committee had thought that my services could have been more useful elsewhere, or if the work could have been undertaken by someone not physically fit. Meanwhile my home has been blitzed, and my practice—representing ten years' hard work—has all but vanished. Wartime sacrifices have not been limited to the armed Forces.

It seems unlikely that the majority of Service M.O.s have spent more than a small proportion of their time in "sitting beside a slit trench" (H. Holden, Nov. 4, p. 610). I remember being visited by an R.N.V.R. friend in the summer of 1941, who, after two years in an armed merchant cruiser, had seen neither enemy submarine nor aeroplane, nor had heard gunfire. On only two nights of that period had he failed to sleep in pyjamas. In those dimly remembered days London was considered "front-line."

The points mentioned by Majors Armstrong and Maddocks are very real disadvantages of Service medicine, but they seem insufficient to justify a conclusion that the work of the rest of us counts for nothing at all. Moreover, Service medicine has some small compensations—rank, variety of experience, travel, popular prestige, and the promised gratuity. Much of the bitterness of these letters might have been avoided if at the outbreak of war we had become a single national medical service, to attend to all, irrespective of uniform or the lack of it.—I am, etc.,

London. "E.M.S."

Death of Robert Burns

SIR,—It was high time that some member of the medical profession made a determined effort to explode the legend that Robert Burns died of drink and dissipation. It is doubtful, however, if Dr. S. Watson Smith has given us the true picture yet. If Mrs. Carswell's facts, as given in her well-documented life of Burns, are correct, it was neither drink nor infective endocarditis which killed the unfortunate poet, but his doctors.

It appears that after many months of joint pains, increasing weakness, and emaciation, Burns was ordered by his physician, Dr. Maxwell, to go to country quarters "and there indulge in sea-bathing, horse exercise, glasses of port wine, and iron water. He was already being heavily dosed with mercury" (p. 443). On June 16, though scarcely able to stand, he went by himself to lodge in a wretched village on the Solway. "Each day he waded shakily—he had to wade a long way to get the required depth—into the chill Atlantic water that he might stand obediently up to his armpits till it was time to drag his aching joints out again and slowly dry himself and sip his allowance of port. Riding was beyond him even if he could have hired a horse, and he had no money." The wonder is that he survived this treatment until July 18, when financial worries drove him home. He arrived in such a feeble, fever-stricken state that he could not climb the stairs to his bedroom, and he collapsed on the kitchen "box-bed," where he breathed his last two days later. But for alcohol he might have died sooner.

Even the lack of the stethoscope and the clinical thermometer hardly explains why Burns fared so ill at the hands of our profession. I am glad to see Dr. Watson Smith making the *amende honorable*.—I am, etc.,

London, S.W.3. LETITIA FAIRFIELD.

Medical Reciprocity

SIR,—Dr. James Burnet's letter on medical reciprocity with France (Jan. 6, p. 27) raises a much wider question on this subject. While expressing no opinion on Dr. Burnet's proposal, I consider that the whole question of reciprocity might be reconsidered in the light of present-day conditions. The English qualification, for example, is not generally accepted in at least one of our Dominions—Canada. Some Provinces accept it, others do not. Surely there should be reciprocity between this country and her Colonies and Dominions before permitting such a state between this country and foreigners.—I am, etc.,

London, N.22. S. CHAPLIN.

"Healthy Industry"

SIR,—It is difficult to understand how the reviewer of my book *Healthy Industry* (Dec. 30, p. 855) could have overlooked or misunderstood that it was written for managements interested in industrial health services. Obviously it was never intended as a discourse for medical men on industrial medical conditions in a factory, hence the omission of medical data redundant to a management of laymen. The annual report so adversely criticized is at least a factual record of work done and results achieved. If, however, the reviewer or any other industrial medical officers with practical experience of this type of work could enhance this report their contribution would be warmly welcomed, not only by myself but by all those engaged in similar work, and incidentally the purpose of this letter will have been achieved.—I am, etc.,

Liverpool. JACK TARSH, M.B., Ch.B.

The Services

Acting Squad. Ldrs. S. Davidson and E. A. G. Goldie, R.A.F.V.R., have been awarded the Air Force Cross.

The following Air Force medical officers have been mentioned in dispatches: Air Vice-Marshal F. C. Cowtan, C.B., K.H.S.; Acting Air Cdre. F. J. Murphy; Gp. Capts. J. D. Leahy, M.C., R. H. Stanbridge; Acting Gp. Capts. R. G. James, A. F. Cook, R. L. C. Fisher, F. E. Lipscomb; Wing Cmdrs. F. G. Mundell and R. Thorpe; Acting Wing Cmdrs. J. G. L. Brown, H. A. Graham, J. G. Stewart, J. L. Brown, J. F. MacCarthy, A. Muir, J. St. C. Polson, J. B. Ross, C. Wollaston, J. R. Cellars, D. J. Dawson; Squad. Ldrs. K. G. Bergin, P. M. Davies, J. H. P. Gauvain (deceased), L. D. A. Hussey, J. M. Kerr, M. L. Maley, A. T. M. Roberts, D. Skinner, W. H. C. Spooner, D. M. Wallace, O.B.E.; Acting Squad Ldrs. C. Bucknall, J. G. Burgess, R. H. Carpenter, G. Clayton, C. V. Gledhill, J. Guthrie, T. A. Hale-Monro, D. W. Higson, W. L. James, A. D. Messent, E. J. G. Murray, T. H. Redfern, C. O. Ribeiro, D. C. Russell, O. Scarborough, W. B. Waterfall; Fl. Lieuts. D. Laing, W. J. Lynd, W. R. K. McParry, F. S. Rickards, J. E. Sharpley, A. Standeven, P. W. G. Sutton, L. A. Sylvester, J. Taylor, R. G. M. Wedderburn, J. H. Wilkins, J. A. J. Wiseman, A. C. Smerdon; Flying Officer H. T. Foot.

CASUALTIES IN THE MEDICAL SERVICES

Killed by enemy action.—Major William Napier, R.A.M.C.

Died in hospital in India.—Capt. Frank Alec Stuart Austen, R.A.M.C.

Wounded.—War Subs. Capts. K. M. Bell, A. Lyell, D. J. Tibbs, J. P. Weiss, R.A.M.C.

Prisoner of war.—Brig. C. H. Stringer, D.S.O., O.B.E.

Universities and Colleges

UNIVERSITY OF LONDON

The following candidates have been approved at the examination indicated:

ACADEMIC POSTGRADUATE DIPLOMA IN MEDICAL RADIOLOGY.—P. C. Bhandari, A. S. Craner, F. Duval, N. Hajdu, A. L. Henderson, H. B. McDowell, J. Noriega, A. P. S. Sanders, A. A. Vickers, J. G. Winternitz.

UNIVERSITY OF DURHAM

At a congregation held on Dec. 22, 1944, the following medical degrees were conferred:

M.D.—[1] Helen Ramsay.

M.S.—E. J. Field; R. A. Fleming, [1] J. Swinney, [1] H. K. Vernon.

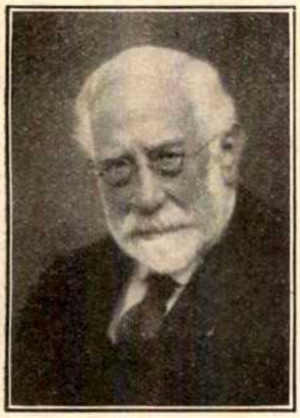
M.B., B.S.—W. R. Argument, Marjorie Bell, A. Bender, R. E. Blakey, A. McK. Brass, Doreen C. Brown, Elspeth M. C. Brown, N. Cardoe, R. G. Chaytor, Joan C. Dickinson, W. H. B. Ellis, A. J. A. Ferguson, A. C. Fleming, F. W. Fordyce, Mary M. Harrison, J. D. Irving, W. Jack, Kathleen D. Knox, Muriel M. Lingwood, J. L. McConchie, Norah Martin, P. Millyard, R. W. J. Naismith, E. M. Norman, G. E. Paget, R. M. S. Parker, A. Pearson, K. Pickworth, W. G. A. Riddle, R. K. Rowntree, Winifred H. Russell, Jane C. Salkeld, R. G. H. Salkeld, Viola E. Shafto, N. A. Sharples, S. G. Siddle, E. Silver, J. E. Stobbs, W. E. Stuart, Elizabeth Troupe, Doreen M. Watson, J. P. Wedderburn, G. E. Welch, J. T. Wheldon, Jean G. Wight, Mary C. Winters, N. E. Wood, N. A. Wynne, J. H. Batchellor.

[1] In absentia.

Obituary

SIR THOMAS BARLOW, Bt., K.C.V.O.
M.D., F.R.S., F.R.C.P.

The doyen of the medical profession died in London on Jan. 12, full of years and honours. Thomas Barlow, the son of James Barlow of Edgworth, Lancashire, a manufacturer in the cotton trade, was born on Sept. 4, 1845. He entered Owens College, Manchester, and remained until 1867, when he took the degree B.Sc.Lond. His career as an undergraduate was very successful: he gained prizes in zoology, geology, and botany, chemistry, physics, and mechanics; he also won the second prize for the Dalton Chemical Essay (1866), and the Dalton Natural History prize. In 1868 he joined the medical school of University College, London, where he continued his successful career, becoming in due time physician assistant to Sir William Jenner and also house-surgeon and obstetric assistant. He took the M.R.C.S. in 1871 and graduated M.B. Lond. in 1873, gaining first-class honours in medicine and honours in other subjects. The M.D. was passed in 1874, when he also began his long and varied experience as a member of the staff of important London hospitals. He was appointed registrar to the Hospital for Sick Children, Great Ormond Street, and in the following year became assistant physician to it, and was elected physician ten years later; he retired to the consulting staff in 1899. In 1876 he was appointed assistant physician to Charing Cross Hospital, but in 1879 he gave up this post for a similar one at the London Hospital. In 1880 his old teachers showed their opinion of his abilities by inviting him to return to University College Hospital as assistant physician. In 1884 he joined the staff of the London Fever Hospital, but retired after four years' service. He was professor of clinical medicine at University College from 1895 to 1907 and was elected professor emeritus in 1911. He retired from the active staff of U.C.H. in 1910.



Barlow's house-physicians and the senior students who attached themselves to him learnt much and realized the immense fund of clinical knowledge stored in his retentive memory. He was in truth a remarkable example of the results that may be obtained in clinical medicine by the method of observation applied in a critical scientific spirit. He would spend an immense amount of time and care on any case which presented a novel combination of symptoms, suggested a new line of inquiry, or the solution of an old problem. Often he would sit lost in thought at the bedside until students grew impatient; but the features of the case were being indelibly fixed in his mind, and the reveries would be ended by a question which sent the clinical clerk home to reflect on the advantages of not being in a hurry. There is little exaggeration in the use of the word "indelibly," for he had the power of recalling for illustration or comparison details of cases he had seen many years earlier. He loved an argumentative conversation on any one of the many clinical subjects in which he was interested; ready to weigh the opinion of others he was tenacious of his own, though prepared to reserve judgment when he felt that more facts were needed. While stress is justly laid on his deep personal interest in clinical medicine, it would be wholly incorrect to give the impression that he was indifferent to experimental medicine or in the least disposed to belittle its results.

Barlow's Contributions to Medicine

His own contributions to medical literature, all founded on clinical observation, were numerous and important. Early in his career he published some valuable work on meningitis. In a paper written with Samuel Gee on cervical opisthotonos in infants (*St. Bartholomew's Hospital Reports*, 1878) simple or basic meningitis (now known as meningococcal meningitis) was differentiated from tuberculous meningitis. Through this work non-tuberculous meningitis was afterwards recognized clinically, but it was not until 1897 that Carr (*Med.-Chir. Trans. Lond.*, **80**), in a paper on "Non-tuberculous Posterior Basic Meningitis in Infants," showed that it should be regarded as a distinct form of meningitis and separate from other forms of the disease secondary to ear diseases and other local infection. Next year Stile isolated the micro-organism and showed that it was practically the same as that isolated by Weichselbaum in the epidemic form of the disease. With D. B. Lees, Barlow wrote the article on simple (posterior basic) meningitis in the first edition of Allbutt's *System of Medicine* (1899); it was founded on clinical and pathological observation of 110 cases. In this article, full of valuable statistics and observations and illustrations, Barlow and Lees differentiated posterior basic meningitis from the vertical type—a distinction not adopted by Batten in the article on meningitis (all forms except the tuberculous) in the second edition of the *System*. Rickets was another disease closely studied by Barlow with his observing mind. He was the first to point out that the sharp drawing of the forefinger over the skin in front of the ear, where the facial nerve emerges, in a child suffering from tetany causes contraction of the muscles of the face. With Lees he inquired into the relationship of congenital syphilis and rickets, and found that in 47% of cases in which craniotabes (thinning of the flat bones of the skull, with bosses on the frontal and occipital bones) occurred in rickets there was a certain history of syphilis. A very important paper was contributed jointly with Warner to the *Transactions* of the International Congress of Medicine, 1881, on the subcutaneous tendinous nodules met with in the acute rheumatism of childhood. The condition had been seen by previous observers, but Barlow and Warner were the first to point out its comparative frequency and clinical significance. Later experience has confirmed the view expressed by these observers, that the nodules indicate concurrent and usually progressive cardiac disease; that a similar process of inflammatory change and proliferation is going on in the fibrous tissues of the cardiac valves or pericardium, or in both; that they indicate grave danger, and a carditis which is uncontrollable and advances almost invariably to a fatal ending. Barlow wrote a paper for this *Journal* (1883, **2**, 511) recording the post-mortem appearances in five cases in which the nodules were present. He came to the opinion that the nodules correspond with the inflammatory exudation which forms the base of the endocardial vegetations in the top of which later on a cap of fibrin may or may not be deposited. In this same paper he stated that he had never been able to assure himself of the production of cardiac murmurs in erythema nodosum, nor of any intercurrent arthritis, however slight. He thought the pains of the disease could be accounted for by effusion into the skin. He held that more evidence was wanted before saying that erythema nodosum was clearly related to rheumatism, much less identical with it, though in some respects it was parallel with it.

In 1883 and 1885 Barlow reported to the Clinical Society of London some observations on Raynaud's disease in which he noted a point that acute observers had overlooked. It was the parallelism between cases of intermittent haemoglobinuria and characteristic cases of Raynaud's disease—those, that is to say, in which the local asphyxia is paroxysmal with a return to the normal state between the attacks. Barlow suggested that possibly other visceral paroxysmal affections might be found, in these cases, comparable with the temporary enlargement of the spleen sometimes found in haemoglobinuria. This suggestion he verified later in a case under his care. He made several other clinical observations on the disease which are to be found in his illuminating article on the subject in Allbutt's *System of Medicine*.

The original work by which Thomas Barlow will probably be best remembered is that connected with infantile scurvy or scurvy rickets. Isolated cases have been recorded as far back as 1651, when in his treatise on rickets Glisson described a complication. German clinicians of last century also recorded cases which they, however, looked upon as examples of acute rickets. The first suggestion of the real nature of the disease was made in 1873 by a Swedish physician, Ingerslev. The first case in England was reported by Sir Thomas Smith in the *Pathological Transactions* (1876), but he called it a case of haemorrhagic periostitis and did not connect it with scurvy. It remained for W. B. Cheadle to describe the disease as true scurvy and trace it to the want of antiscorbutic element in the food. This he did in 1878 in a clinical lecture based on three cases. In later years Cheadle recorded more cases and other clinicians added to the list. Barlow then became interested in the subject and in 1883 published the result of his observations in the *Transactions of the Medico-Chirurgical Society*, recording 31 cases, several of which he had seen in his own practice, and giving an exhaustive account of the pathological changes in three cases. This paper is looked upon as completing the investigation of the disease and adding the final proof that the lesions found in it are identical with those met with in the so-called sea or true scurvy of adults. He returned to the subject in his Bradshaw Lecture before the Royal College of Physicians in 1894, when he brought evidence gleaned from later experience to support his original description. This work greatly impressed German scientists, who declared their appreciation of it by calling the disease after him—"die Barlow'sche Krankheit." The important effect which the discovery of the real cause had on infant feeding at a time when artificial foods and sterilized milk were becoming very popular cannot easily be exaggerated; but Barlow spoke with great caution because he was fully alive to the urgent and great risks that might attend the use of unsterilized milk. Half a century later, in 1935, when he reached the age of 90, the *Archives of Disease in Childhood* made its August issue a special tribute to the importance of his work on infantile scurvy. It reprinted his original paper from the *Medical Chirurgical Transactions* (1883, **66**, 159), "On Cases described as 'Acute Rickets' which are probably a Combination of Scurvy and Rickets, the Scurvy being an Essential and the Rickets a Variable Element." In a contribution to the birthday number Sir Frederic Still showed that thanks to it the disease became recognized much earlier and feeding corrected so that children were spared months of suffering and many lives saved. Thus of 35 cases recorded by Barlow, 20 were over 1 year old and approximately 1 in 4.5 had died; whereas of the 155 seen by Still the majority were between the ages of 6 and 12 months and the mortality almost exactly 1 in 18. As further homage to Barlow were other writings by American and Continental physicians on the very early recognition of infantile scurvy by radiological examination; latent scurvy; scorbutic dystrophy; and the identification of vitamin C of the citrus fruits so much used in prevention of the disease.

In a foreword to the birthday tribute in 1935 Lord Horder described it as a collection of essays written in honour of a man who was so easily and so notably the doyen of British medicine. ". . . Though it is many years since his colleagues have been deprived of that wealth of experience, sound judgment, and cheery helpfulness they invariably got from him, he has retained an active interest in many affairs that have as their object human betterment in general and the welfare of the medical profession in particular. He has continued until now to infuse vitality into every institution and movement in which he has taken a part." "But of Barlow it might be said more truly than of any of his contemporaries that he is of no one school, but of all . . . he has been too great to be parochialized." A visit that afforded him and his Lancashire friends much pleasure was paid in his ninetieth year to take part in the celebration of the centenary of the Manchester Medical Society, of which he had been an honorary member for many years.

Sir Thomas Barlow became a Fellow of the Royal College of Physicians of London in 1880, and has long headed the list. He was Censor in 1905 and 1906, and was elected President in 1910; he was re-elected four times. The medical events during his tenure of the office were two. One was the introduction of the National Insurance Act and the controversy to which it gave rise. Barlow never declared his own opinion very clearly, but probably he was in favour of the principle the Act embodied. The second was the International Medical Congress held in London in 1913, over which he presided. In 1916 he gave the Harveian Oration on "Harvey: the Man and the Physician." He was Physician Extraordinary to Queen Victoria and was in attendance during her last illness; he was continued in the same office by King Edward VII and King George V. He was created a baronet in 1900 and K.C.V.O. in the following year. He was elected F.R.S. in 1909, and at various times received honorary degrees from the Universities of Aberdeen, St. Andrews, Edinburgh, Durham, Harvard, Montreal, Toronto, Christiania, Dublin, and the Victoria University of Manchester.

Barlow joined the B.M.A. as long ago as 1873. He served as secretary of the Section of Medicine in 1884, was vice-president of the same Section in 1891 and its president in 1906. He was also president of the Section of Diseases of Children in 1893, and in 1902 he gave the Address in Medicine before the Annual Meeting of the B.M.A. at Manchester. In 1918 he was elected an honorary member of the Société Médicale des Hôpitaux de Paris. He was awarded the gold medal of the Royal Society of Medicine in 1932, receiving it in person, at the age of 87, at the annual dinner of the Society.

Personal Traits

He was a fine specimen of a Lancashire man. Short and sturdy in build, his features bore the stamp of robust common sense with which he was richly endowed. Combining shrewdness in thought, directness in action, and openness in speech with a wide and thorough knowledge of clinical medicine he attained the highest position in London as a consultant, and no London physician was more highly thought of by his fellow practitioners in the county of his birth; many a time and oft were cases sent to him by them for his opinion: they knew that they would get practical and valuable advice from him. Home visits to the village where his brother's mills were afforded him great pleasure, for he had a deep affection for his own people, among whom he liked to be. His success as a physician was due in great part to his personality; his kindliness of heart, his sympathetic nature won the confidence and trust of patients, young and old, and of the anxious relatives. His attitude to patients has been well described by the poet-physician Robert Bridges in his *Recollections*; there is also an excellent and rather moving account of him as clinical teacher at Great Ormond Street in *Behind the Night Bell* (1938) by the late Dr. F. G. Layton: "He had a sort of intuitive flair for diagnosis. He had more than that. He had the knack of saying always the kind thing. The old Queen did well when she chose him as one of her advisers. He was very blunt; he was very rugged—he came from the North Country; he was fundamentally honest. It is forty years since I last spoke to him, but I love him to-day as I loved him forty years ago. I still feel that I owe him more than I can ever repay. He more than anybody else taught me the merits of humanism as applied to medicine; and he did it not by any deliberately spoken word but by just being himself."

After his retirement, and up to the last, Sir Thomas Barlow remained a still active figure in the eyes of the profession through his whole-hearted work as president of the Royal Medical Benevolent Fund since 1920. Himself a generous supporter of the charity, he wrote letters to the medical journals every year asking for contributions to its Christmas Gift Fund. He married in 1880 the daughter of Patrick Dalmahoy of Edinburgh, and leaves two sons and a daughter. His eldest son, Sir Alan Barlow, entered the Civil Service and is Second Secretary to the Treasury. His second son, Sir T. D. Barlow, carried on the family business in Manchester and Bolton, and is now Director-General of Civilian Clothing at the Board of Trade. A third son died on active service in the last war. During the long evening of his days Sir Thomas was tended with unwearying care by his daughter Helen.

WALTER ESSEX WYNTER, M.D., F.R.C.P.

On Jan. 4 the death took place at Newbury of Walter Essex Wynter, aged 84, consulting physician to the Middlesex Hospital, where he was over a long period of years both beloved and respected by many generations of students and house-physicians. He was the son of Andrew Wynter, M.D., editor of the *British Medical Journal* 1855–61, was born in 1860, and was educated at Epsom College, on the council of which he afterwards served for many years, and at Middlesex and St. Bartholomew's Hospitals. He qualified as M.R.C.S. in 1883 and became

F.R.C.S. in 1885, but he gave up surgery in favour of medicine, took the M.B.Lond. (with honours) in 1887, the M.D. in 1888, and became F.R.C.P. in 1897. Elected to the staff at Middlesex he soon established a high reputation not merely as a physician but as a very fine teacher; and this at a time when Middlesex had several other remarkable personalities on the teaching staff (e.g., Bland-Sutton). He published two books in his early days—*A Manual of Clinical and Practical Pathology* in 1890, and *Minor Medicine* in 1891.

Wynter had a strongly built sturdy frame, with a rubicund and cheerful countenance, and was a man of boundless energy. As the *Times* has indicated, he was independent of private practice, but worked hard in his wards and in his teaching rounds from pure enthusiasm. When he retired from London, a good many years ago, he discovered on the edge of Newbury (and almost next door to the district hospital there) a semi-derelict manor house, whose ground floor was being used as a store for builders' ladders, wheelbarrows, and other stock-in-trade. This he bought and very lovingly restored: upstairs is some of the oak timber of the original building (of 1330), downstairs a charming room with herring-bone red brick work and oak panelling dating from 1550—he used to speak of this as the "modern improvements" then undertaken. This treasure —Bartholomew Manor—with a beautiful old-world garden, he was never tired of displaying to any visitors. Within the same curtilage stands another very ancient building, which Wynter converted into a hostel for retired nurses; of this a full account was given in the *Journal* of Feb. 19, 1938. It is understood that he has provided an endowment fund, to be administered by the Middlesex Hospital, to keep in being this splendid work of practical (and much-needed) philanthropy. Another of his interests, as has been mentioned, was his old school, Epsom College. After the last war his brother, the late Dr. Andrew Wynter, handed his war gratuity to the college to accumulate at compound interest until it should be sufficient to found a scholarship; to this gift Walter added very considerably, and the fund now stands at just about the goal the two brothers had in view—namely, £1,000. At Newbury Walter Wynter was of great value as physician to the district hospital; he also served for several years on the town council and rendered immense service as chairman of the public health committee. When about 70 years of age he was advised to submit to amputation of one leg above the knee; naturally his friends began to entertain forebodings for him, but he "never turned a hair" after the operation, and soon became as active and energetic as ever. He was of a most amiable and cheerful disposition; a correspondent says rightly that he can hardly have had a single enemy. He married Ada Margaret, daughter of Samuel Wills of Bristol; they had no children, and Mrs. Wynter died in 1937.

Surg. Rear-Adml. GORDON GORDON-TAYLOR writes:

May I offer a tribute to the extraordinary charm of Walter Essex Wynter and to his surgical "angle." Wynter's interest in surgery remained throughout his professional career; he taught for some years along with Bland-Sutton in the anatomical department of Middlesex Hospital. Destined himself to the practice of medicine, he rarely missed an occasion to attend the operating theatre when any case from his medical wards was being operated on, and fortune happily seemed to ordain that during most of the years of his service at Middlesex his "corresponding" surgeon was his friend Sir John Bland-Sutton, whom he ardently admired. Although a physician, he performed for the first time the operation of lumbar puncture, and he often ventured to suggest ingenious methods for dealing with commonplace maladies: in the period which preceded the era of liver therapy for pernicious anaemia many a spleen was removed at Wynter's suggestion by Bland-Sutton and the writer, with results which contrasted favourably with those of medical therapy in the treatment of the disease at that time. He had bizarre notions for getting rid of abdominal ascites without the systemic loss of fluid which attends recurrent tapping, and for a period of time "crural drainage" was a fashionable method of treatment for this condition in his wards. He had a passion for exploring new therapeutic preparations; many were soon discarded, but the writer recalls a more prolonged trial of a preparation—tinctura apocyani, which he termed the "vegetable trocar"—in cases of ascites. Wynter will long be remembered by his contemporaries and pupils for his unvarying kindness and charm; he had a most lovable nature and could not have had an enemy in the world. He is said to have grown his own tobacco in his garden at Newbury and to have smoked it green; some have alleged that this practice may have had some share in the malady from which he suffered for the last 15 years of his life. He endured much pain and surgical mutilation; but his affliction he bore with his customary fortitude, equanimity, and cheerfulness, even during the final period of his life, when the advance of crippling disease precluded him from wielding the rod and reel of the craft of which he was so devoted and skilful an exponent.

JOSEPH GRIFFITHS, C.M.G., M.D.Ed., M.Ch.Camb., F.R.C.S.

The death of Dr. Joseph Griffiths on Jan. 3 at Cambridge removes the surgical doyen of that town, where he had practised with conspicuous success during almost the whole of his long professional career. He was 81 at the time of his death, and qualified as M.B.Ed. in 1885, almost 60 years ago; he took the D.P.H. (of Cambridge) in 1887, M.D. in 1890, F.R.C.S. in 1892, and M.A., M.Ch. in 1907. After the death of Sir George Humphry in the middle 'nineties the professorship of surgery at Cambridge remained vacant for several years until the appointment of Howard Marsh; during part of this time the teaching of the subject was in the hands of Joseph Griffiths, who was reader in surgery from 1897 to 1902. He was then quite a young surgeon, though with an already established reputation as a careful and reliable exponent of his specialty. Widely known and liked as "Joe," he was of great value to Addenbrooke's at a time when that hospital was rather short of capable surgeons—a deficiency supplied later when Roderick, Cooke, and others started practice in the town. Griffiths was a tiny little man physically, but of abounding energy and enthusiasm. During the 1914–18 war he was O.C. the 1st Eastern General Hospital, with the rank of colonel, and was awarded the C.M.G. for his services. He had also been surgeon to the St. Leonard's Hospital, Sudbury; and was Hunterian Professor at the Royal College of Surgeons in 1894 and 1895.

A Cambridge colleague writes:

Griffiths added a large number of pathological specimens to the Museum, especially bone preparations, having evolved, with the help of his laboratory assistant, Frederick Izzard, a method of maceration which produced beautifully white specimens of bone diseases which were the constant admiration of generations of surgical examiners. He also had a large private collection which he presented to the Royal College of Surgeons. At the time of his death Griffiths was senior consulting surgeon to Addenbrooke's Hospital, having served on the honorary staff since 1892; he was also consulting surgeon to the Huntingdon County Hospital. In the last war he was in command of the 1st Eastern General Hospital, which was located in Cambridge. It was mobilized on Aug. 5, 1914, at the Leys School; it subsequently moved to Neville's Court, Trinity College, and finally to an open-air hutted hospital built on the King's and Clare cricket ground. The open-air ward was Col. Griffiths's own idea, and was thought by many to be too spartan, but it proved of undoubted benefit to the patients, and the advantage was brought home to those in attendance when a convoy of wounded Belgians arrived from France with very foul wounds. A farmer's son born in Carmarthenshire, he took up farming as a hobby, and in earlier years followed the hounds. He was a keen horseman, and also took a warm interest in animal pathology. He was honorary secretary of the Cambridge Medical Society, 1889–96, vice-president 1897–1900, and president 1901.

T. N. KELYNACK, M.D.

Mr. HUGH REID, F.R.C.S., of Liverpool, sends the following appreciation:

Nearly twenty years ago I met Dr. Kelynack for the first time. I had come back from a holiday in Switzerland and the talk naturally turned on mountains and snow and sunshine. I soon learned that his wide knowledge of people and places and particularly of sick children had taken him out to Montana and other centres to see for himself the conditions of sanatorium life. This ubiquitousness was characteristic of the man. If we talked of Derby or Liverpool or Edinburgh, Dr. Kelynack had been there; he knew the clinics, or the M.O.H., or a friend, or he had given a lecture or attended a hospital. His friendliness, his sympathetic interest, his warm and cheerful welcome at this first interview made me instantly and comfortably at home in his house. Young people of all ages took to him at once. His knowledge touched their interests and drew them out however shy they might have been—drew them out to discuss not only medicine but the philosophy of life and living.

My respect and admiration soon ripened into an affectionate friendship as I learned to know him better. His whole home radiated an air of joyous and purposeful living complemented by the influence of his brilliant doctor wife and his medical-student daughter, afterwards destined to become Assistant Secretary to the B.M.A. One interesting incident stands out in my memory of Mrs. Kelynack's practical efficiency. I had come down from Liverpool to stay at Harpenden, and one evening went off to London to one of the hotels for a dance, intending to go back to Liverpool the following morning. Towards midnight a telephone message came to Harpenden from a doctor in Southport asking me to perform an urgent operation. I had not thought of informing my host and hostess as to my whereabouts, but, nothing daunted, Mrs. Kelynack rang up a number of hotels in London, giving my description. Before 12.30 a waiter walked up to the table where I was sitting, asked me if I were the person described, gave me the message, which enabled me to spring into a taxi to catch the 12.40 from Euston. Mrs. Kelynack knew the value of time should an emergency arise. Her own activities fitted in with her husband's more leisurely outlook on life. It is easy to see how he came to lean on her guidance and care. One sometimes hears that an ideally happy marriage is somewhat of a rarity, but to stay with them was to see the working out of such a state in real life. His knowledge of the minds of little children with whom he was so intimately associated seemed to contribute to his directness and simplicity of outlook.

His latter years were clouded by the loss of his wife. He lost his resilience and his mainspring for existence. Now he lies buried in the grounds of the Children's Home in Harpenden side by side with the one whom he loved so well. The obituary notice in the *Times* gives an account of his academic distinctions, his wide activities, and the mark he made in his professional life. We who are left remember also his urbane and joyous personality, ready to encourage, ready to help, and ready to inspire.

Dr. **ROBERT MUSCHAMP**, one-time M.O.H. for Guiseley and Yeadon, a former chairman and member for about 20 years of Guiseley Urban Council, and for 12 years a member of the West Riding County Council, died in retirement on Jan. 4, aged 79. He studied medicine at Leeds, qualified in 1892, and was a Fellow of the Society of Medical Officers of Health. He is survived by his widow, a son, Dr. A. Muschamp, and two daughters, Dr. May Muschamp and Dr. Evelyn Muschamp, all three of whom are in practice in Guiseley and Yeadon.

Dr. **JAMES RICHARD WHITWELL**, formerly medical superintendent of St. Audry's Hospital, Melton, Suffolk, died suddenly on Jan. 9 in London, aged 81. The son of a medical man he was educated at Shrewsbury School and Edinburgh University, where he graduated M.B., C.M. with honours in 1887, and later studied in Berlin and Vienna. Before his appointment to St. Audry's he had been pathologist to the West Riding Mental Hospital, Sheffield, and assistant medical officer at Menston, Leeds. For many years he was honorary librarian of the Royal Medico-Psychological Association and a member of council of the Mental After-care Association and the Lebanon Hospital, Syria. Dr. Whitwell joined the B.M.A. in 1890, was secretary of the Section of Psychology at the Annual Meeting of 1900, and president of the Suffolk Branch in 1923–4. He gave the first description of the microscopical changes in the central nervous system in myxoedema in these columns on Feb. 27, 1892 (p. 430), and was the author of *Gleanings from Plato* (1935), *Historical Notes on Psychiatry* (1936), and *Syphilis in Earlier Days* (1940).

Although it is 25 years since Dr. **JAMES DUNLOP** retired from active practice, he is still well remembered in Essex, especially Aveley and Upminster, where he practised for many years. James Dunlop was born at Biggar, Lanarkshire, in 1862. He took the degree of M.A. in 1882 and the M.B., C.M. Glasgow in 1885, and then practised in Aveley and Upminster until 1920. During the 1914–18 war he had sole charge of 49th Wing, R.A.F., at Upminster, near Hornchurch Aerodrome. In 1921 he sustained a fracture of the odontoid process from a railway accident and retired to live in London. A colleague writes: He was a great man, a wonderful father and companion; very witty and of a happy disposition and so modest. He was very fond of sport and spent most of his spare time in the summer at Lord's Cricket Ground, becoming a member of Middlesex Club. He married Margaret Crawford Vallance and leaves three daughters. He died on Dec. 10, 1944, at the age of 82.

The following well-known medical men have died abroad: Dr. **VICENTE BATISTA**, paediatrician of Sao Paulo, Brazil, aged 48; Dr. **HENRY KENNON DUNHAM**, ex-president of the United States Association against Tuberculosis; Dr. **JOAO DE CAMARGO**, the Brazilian gynaecologist, aged 52; and Dr. **LUIZ ANTONIO DA SILVA SANTOS**, ex-dean of the faculty of medicine of Rio de Janeiro, aged 90.

Medical News

A meeting of the Medico-Legal Society will be held at 26, Portland Place, W., on Thursday, Jan. 25, at 4.45 p.m., when Mr. Hugh N. Linstead, M.P., will read a paper on "The Pharmacy and Medicines Act, 1941, and the Sale of Proprietary Medicines."

A conference to discuss the use of science in the post-war world, which is being organized by the Association of Scientific Workers, will be held at Caxton Hall, London, S.W., on Feb. 17 and 18. The object is to draw attention to the need for using science as fully in peacetime as in war. Further particulars may be obtained from the association at Hanover House, 73, High Holborn, W.C.1.

The gold medal for distinguished services in medicine of the New York Academy of Medicine has been presented to Dr. Oswald Avery, emeritus member of the Rockefeller Institute for Medical Research, in recognition of his investigations that "have led to discoveries and great advances in the science of bacteriology."

The seventy-fifth birthday of Vladimir Komarov, president of the Academy of Sciences of the U.S.S.R., and the fiftieth anniversary of his activities as a scientific worker were celebrated on Oct. 15, 1944.

A new Department of Physical Medicine and Rehabilitation to replace the one destroyed by bombing in 1940 was opened by Miss Florence Horsbrugh, Parliamentary Secretary to the Ministry of Health, at the Prince of Wales's General Hospital, Tottenham, on Dec. 20.

A meeting of the directors of the Society for Relief of Widows and Orphans of Medical Men was held on Jan. 3, with Dr. R. A. Young, president, in the chair. A legacy of £5,000 from Dr. C. Reid of Stafford was reported. At Christmas £1,100 was distributed as a present, each widow receiving £20. The half-yearly grants paid this month amounted to £1,948. Membership is open to any registered medical man who at the time of his election is residing within a twenty-mile radius of Charing Cross; full particulars may be obtained from the secretary. Election is by ballot and at the discretion of the Court of Directors. Members are reminded that their annual subscriptions are now due. The secretary attends at 11, Chandos Street, Cavendish Square, W., on Wednesdays from 4 to 5 p.m.

The medical committee of the Scientific Film Association has just published its first *Handlist of Films of Medical Interest*. This lists twelve recent films with a brief synopsis of their content and gives details of where to get them. Such lists, which it will publish at intervals, can be obtained from the honorary secretary. The committee also announces that it is now preparing a series of film programmes to be presented on the fourth Thursdays in February, March, April, and May at 5.30 and again at 8 p.m. A season ticket admitting to all four shows will be issued at a nominal charge of 3s. Application should be made immediately to the honorary secretary of the Medical Committee, Dr. S. J. Reynolds, 14, Hopton Road, S.W.16.

Dr. Dellepiane Rawson, an eminent plastic surgeon in the Argentine, has arrived in this country for a six-months visit arranged by the British Council. He is head of the special ward for plastic and restorative surgery at the Hospital Rawson, Buenos Aires, and associate teacher at the Faculty of Medicine, and will be working in the E.M.S. plastic surgery unit at Park Prewett Hospital, Basingstoke, with Sir Harold Gillies.

The 21st annual report of the Ella Sachs Plotz Foundation for the Advancement of Scientific Investigation records eighteen grants made during 1944 and gives a list of the investigators and the purposes of the research aided. Three workers in Great Britain received grants—Dr. N. Ambache, Guy's Hospital, for investigation of the action of tetanus toxin on synaptic junctions; Dr. P. Ellinger, of the Lister Institute, for investigation into nicotinamide metabolism in various deficiency diseases; and Dr. A. H. T. Robb-Smith, of the Radcliffe Infirmary, Oxford, for an attempt to standardize haemoglobinometry. In making the awards the trustees favour researches that are directed towards solutions of problems of medicine and surgery or in branches of science bearing on medicine and surgery. As a general rule preference is given to researches on a single problem or on closely allied problems. Applications for the year 1945–6 must reach the secretary of the Executive Committee, Dr. Joseph C. Aub, Massachusetts General Hospital, Fruit Street, Boston 14, Massachusetts, before April next. Letters asking for aid must give the qualifications of the investigator, an accurate description of the research, the size of the grant requested, and the specific use of the money to be expended. It is highly desirable to include letters of recommendation from the directors of the departments in which the work is to be done.

On Wednesday, Jan. 24, at 1.45 p.m. at the Royal Society of Arts, John Adam Street, London, W.C.2, a paper on forensic science will be read by J. B. Firth, D.Sc., F.R.I.C., M.I.Chem.E., director of the North-Western Forensic Science Laboratory. A sandwich lunch, which should be ordered in advance, will be served from 1 to 1.30 p.m. at 1s. 6d. per head. Invitation cards to the lecture may be obtained on request from the R.S.A.

Mr. W. S. Morrison, Minister of Town and Country Planning, will open on Feb. 1 in the Victoria Art Gallery, Bath, an exhibition of maps, drawings, and models of the proposed scheme for the reconstruction and replanning of Bath and the surrounding area. The scheme has been prepared for the Bath and District Joint Planning Committee by Sir Patrick Abercrombie in conjunction with the city engineer and the planning officer.

Prof. Pasteur Valery-Radot has been elected member of the Académie des Sciences and Dr. Georges Duhamel has been appointed permanent-secretary.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* there were 437 more cases of measles than last week, and 97 more of acute pneumonia. Notifications of scarlet fever fell by 394, those for whooping-cough by 138, those for dysentery by 50, and those for diphtheria by 10.

Lancashire reported 88 fewer cases of scarlet fever than last week, and Staffordshire 40; in Lancashire the total for whooping-cough fell by 38. Diphtheria notifications showed a drop of 11 in Northumberland. Notifications for this disease stand at about half the usual winter level. The local trends of measles fluctuated considerably: Middlesex reported a rise of 147, Derbyshire of 77, Yorks North Riding of 76, Durham of 74, Surrey of 68, and Kent of 60; in Lancashire and Cheshire the incidence dropped by 190 and 111 respectively.

The 123 notifications of dysentery are the smallest weekly total recorded during the year, although in Essex the cases rose from 7 to 23. The only other large returns were those of Lancashire and London with respectively 24 and 16 cases.

In *Scotland* measles notifications rose by 132, and diphtheria by 19, but those for whooping-cough dropped by 64, and for dysentery by 32. Of the 101 cases of dysentery, 33 were reported in Lanark County and 29 in Glasgow.

In *Eire* there was a serious rise in diphtheria notifications —81 more cases than in the preceding week; 47 cases were notified in Dublin C.B., and the remaining 144 were spread over fifty-nine registration areas.

In *Northern Ireland* measles notifications fell from 248 to 188; all but 10 cases were reported from Belfast C.B.

The Health of Edinburgh

The provisional returns for 1944 show that the births, 7,907, were the highest for eighteen years, and the deaths, 5,995, were the lowest since 1938. The infant mortality was 51 per 1,000 births—the lowest on record; 12 deaths were attributed to diphtheria, the lowest total since immunization was first introduced twenty-two years ago. During this period only 7 deaths have occurred among immunized children, compared with 868 among non-immunized, and in the last seventeen years no deaths had occurred among the immunized children. Deaths from pulmonary tuberculosis numbered 254, and 49 from non-pulmonary, compared with an average for the preceding five years of 301 and 73.

Quarterly Returns for Northern Ireland

The birth rate during the September quarter was 22.8 per 1,000, being 1.0 below the rate for the third quarter of 1943 but 1.0 above the average of the third quarters of the five years 1939-43. Infant mortality was 56 per 1,000 registered births, the lowest rate recorded during the present war, and 12 below the average of the five preceding September quarters. Maternal mortality was 2.8 per 1,000 births—0.6 below the five-years average. The general death rate was 10.6 per 1,000—0.8 below the average. Deaths from the principal epidemic diseases were equivalent to a rate of 0.42, which is the lowest for over twelve years. Of the 139 deaths included under this heading, 90 were attributed to diarrhoea and enteritis, 23 to whooping-cough, and 11 to diphtheria. Deaths from pulmonary and non-pulmonary tuberculosis were 194 and 64, compared with 207 and 69 for the average of the five preceding third quarters.

Week Ending January 6

The returns of infectious diseases during the week in England and Wales included: scarlet fever 1,462, whooping-cough 1,538, diphtheria 439, measles 11,947, acute pneumonia 1,242, cerebrospinal fever 49, dysentery 204, paratyphoid 1, typhoid 8. Influenza deaths in the 126 great towns numbered 55.

No. 52

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Dec. 30.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

---

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent, London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Bismuth for Osteo-arthritis

Q.—*Is there any evidence that bismuth is of value in the treatment of osteo-arthritis, and has it any advantages over gold? In the case I am interested in, both knees and the right hip are affected.*

A.—Bismuthi et sodii tartras has been extensively used for the treatment of yaws, and in view of the fact that in this disease rheumatic pains are often a feature and arthritic changes in the joints occur in the later stages, it was thought to be worthy of trial in other forms of arthritis. It was included in the *British Pharmacopoeia* in 1936. The published results of its use in this country in various forms of arthritis are as yet too scanty to establish its value, but it is said to be less effective in osteo-arthritis than in other forms. In the case which is the subject of this question the arthritis of the hip is probably the primary trouble, and the knee changes are secondary to it and due to abnormal strain setting up a chronic synovitis and later osteo-arthritic changes—a very unpromising type of case for any form of treatment; gold would almost certainly be useless. In other forms of arthritis the experience of the writer has been that the bismuth salt is definitely inferior to gold in the treatment of rheumatoid arthritis, but that where gold has been found ineffective or has produced toxic reactions the bismuth salt should be tried; the results, however, have not thus far been very encouraging. No harmful reactions have been met with in the comparatively few cases in which it has been used, and this would justify its further trial in these intractable conditions.

"The Four Humours"

Q.—*Patients frequently talk about their blood being "out of order" or "overheated," and thus explain, for example, children's spots. In the same strain they accuse themselves of "making too much acid," or say that everything they eat "turns to acid," with apparently no reference to hyperchlorhydria. What is the pathology, if any, to which they refer? What is the treatment, apart from the "cooling magnesia" which the patients usually prescribe?*

A.—The calorific value of a food depends on its content of protein, fat, and carbohydrate. After combustion in the body it leaves a residue which may be alkaline or acid. These data are tabulated in textbooks of dietetics, from which it will be seen that fats are heating and meat and cereals form acid. It is clear, however, that patients do not have these matters in mind when making the statements quoted. More probably we are dealing with garbled recollections of the humoral pathology which was first developed by the school of Cos (400 B.C.) but persisted well into the nineteenth century. Just as there were four elements in Greek philosophy (air, water, fire, and earth), so there were four qualities (moisture, cold, warmth, and dryness) and four humours (the blood, the phlegm, the yellow bile, and the black bile). Certain symptoms of disease represented the effort of the body to preserve life through coction or cooking of the altered fluids. The blood was warm and moist, like air, and sanguineous disorders were common in the spring. Sylvius (1614–72) added the notion that acid and alkaline elements were normally balanced in the circulating blood, and that illness was due to a disturbance of this equilibrium. He therefore distinguished diseases due to excess of alkali on the one hand and diseases due to excess of acid on the other, and advised treatment in accordance. Ideas of coction were much affected by Stahl's theory of phlogiston, which was conceived as the principle of inflammability, and subsequent developments led to treatment by powerful antiphlogistic regimens, particularly blood-letting and purgation. Many of us have childhood memories of brimstone and treacle every spring as a result of these hypotheses.

From a broader standpoint, it might be argued that an inherent weakness in the mental make-up of *Homo sapiens* is a tendency to form myths or irrational ideas about food. This constitutes an important chapter of Freudian psychology. Patients imply that it is their food which is overheating or turning to acid, thus revealing unconscious fears of poisoning, oral impregnation, etc. The modern fashion is to ascribe heat spots in children to food allergy or digestive disorder. Acid fruits, pork, breakfast cereals, chocolates, and sweets are forbidden and a mild aperient and alkalis are prescribed. Thus fashions may change, but in treatment we have not advanced far along the road beyond Sylvius and Stahl. Acidity, as distinct from heartburn or acid regurgitation, is a mythical malady. Acidosis was a common diagnosis in the first flush of biochemical medicine after the last war, and it is still the subject of propaganda by the manufacturers of proprietary salines. However, in the adult at any rate, acidosis occurs only in the presence of profound and obvious disturbances of bodily function. A more precise description of the sensation should be demanded from the patient. In some cases the symptoms of the syndrome of reversed peristalsis may be present—belching, nausea, biliousness, coated tongue, bad breath, etc. The cause may be a reflex dyspepsia or a mental disturbance. Here again an aperient may restore the normal gradient. If there is no physical counterpart of the complaint of acidity, a purely psychic disorder should be suspected.

Industrial Dermatitis in Coal-miners

Q.—*What are the causes of industrial dermatitis in coal-miners? How can one differentiate this condition from non-industrial dermatitis?*

A.—Among the causes of industrial dermatitis in coal-miners are: acids and alkalis; grease and oil; cement (among "sinkers"). "Heat rashes" may occur where working conditions are hot and humidity high. Trauma is sometimes instrumental in determining the site of a dermatitis the primary cause of which may be one or more of the above. The differential diagnosis of industrial from non-industrial dermatitis calls for the same discrimination among coal-miners as with other "workmen." Of assistance in the differential diagnosis are a careful history with a knowledge of working conditions, and due appreciation of the significance of such points as occurrence and distribution of the dermatitis. Ringworm infections of the skin, which are favoured by heat and moisture, should be borne in mind.

Medicinal Treatment of Urinary Calculi

Q.—*How should one set about the removal of renal calculi by medicinal means? Is lavage of the kidney pelvis now used for removal of calculi in that situation?*

A.—There are two methods of treating renal calculi by "medicinal" means—the local application of solutions introduced into the renal pelvis through either a ureteric catheter or a nephrostomy tube; and the regulation of the reaction of the urine by diet and drugs. Apart from prophylaxis, these methods are used almost entirely for phosphatic stones, or even accumulations of phosphatic deposit which are only loosely bound into stones; for dense stones very prolonged treatment is required, and the technical difficulties are very great. A full description of the solutions used and the details of the method of keeping up the concentration of the solution in the renal pelvis are given in a paper by Suby and Albright (*New Engl. J. Med.*, 1943, **228**, 81). From this it will be realized that constant skilled nursing is essential for success, but the results obtained should encourage others to try. There are many articles and books on the dietetic treatment of urinary lithiasis, but the basis of the method may be briefly stated thus: to produce an alkaline urine the diet should be mainly vegetarian, while an acid urine is obtained by giving a diet rich in proteins and fats but poor in sugar.

Intravenous Anaesthesia for Torn Perineum

Q.—*Is intravenous anaesthesia suitable for use in performing a repair of a torn perineum (presuming the patient's general condition is good)?*

A.—For primary repair of the torn perineum immediately after delivery local analgesia is unsurpassed and has the advantage of complete safety. It is also an extremely simple procedure and ideal for the practitioner working single-handed, since the anxiety of caring for an unconscious patient while occupied in inserting sutures into the perineum is eliminated. In cases where a general anaesthetic is given for the delivery—e.g., in forceps cases—there is no objection, if the patient's condition is good, to continuing light general anaesthesia while the perineum is repaired.

General anaesthesia should not, in our opinion, be used in order simply to repair the perineum except in the case of a very severe tear involving the rectum. Here the repair is a major operative procedure and should be carried out under the best possible conditions. For such a case general anaesthesia is probably the best, and there seems to be no objection to the use of intravenous anaesthetics, provided the usual precautions are observed—e.g., a good airway is maintained and resuscitatory measures such as nikethamide are available.

"Apple Diet" for Infantile Diarrhoea

Q.—*What is the "apple diet" for diarrhoea in infants or children? How is it prescribed? What substances in the apple exert a therapeutic effect; and what is the action of each?*

A.—Apple diet has been used effectively for acute colitis and dysentery in children, and in infants for the later stages of diarrhoea when dehydration has been overcome but the stools remain offensive. Raw sweet apples are used, peeled, cored, and then grated, and the pulp mashed, each feed being freshly prepared. For a child of about a year some 10 apples a day will be necessary. The equivalent of 2 or 3 apples is given every 3 or 4 hours for 2 or 3 days. During this time all other food is withheld, but water must be given—2½ oz. per lb. body weight per day—sweetened if necessary with saccharine or flavoured slightly as weak tea (without milk). A slow return to normal diet is then begun. It is thought that "pectin" in the apple is the important agent, possibly acting by absorbing toxins or causing some alteration in bacterial flora. It can hardly be said that the scientific basis for what is essentially an old-fashioned Bavarian peasant remedy has been fairly established.

Anencephaly

Q.—*After bearing a normal female child, now 6 years old, a woman produced in two successive pregnancies an anencephalic monster, the first of which apparently died 3 weeks before delivery. In the second case the pregnancy was terminated 1 month early, as the mother was suffering from high blood pressure and albuminuria. So far as can be ascertained there are no abnormalities in the woman's family, and no intermarriages have occurred as far back as can be traced. Her husband's paternal grandparents were first cousins. A sister of his suffers from epilepsy, but apart from some deafness and another sister who had rheumatic fever, the medical histories of his close relatives are good. After the second anencephalic monster was born a blood examination was done, with negative result. What are the chances of a normal child resulting from any future pregnancy? The husband has asked my opinion on the advisability of sterilization of himself or his wife.*

A.—As many as three successive anencephalic monsters have been born to normal parents, and it is quite possible that the next child may be anencephalic. The chances of its being normal cannot be stated with certainty. Sterilization of either the father or the mother is inadvisable. One objection to it is that, if either parent died, the other might marry again and wish to have children.

Fungus on Tongue

Q.—*A man 38 years old has had for 10 years at least, possibly more, a thick yellowish-green fur on the dorsum of the tongue. He was told by an eminent Italian physician that the condition was due to an over-abundance of fungus which is normally present on the tongue. Is this a correct explanation? Is there any treatment? I have not been able to find any description of such a condition in the literature.*

A.—Apart from pathogenic fungi, such as *Candida albicans* (the common thrush fungus), which may cause a specific mycotic glossitis, moulds and yeasts are sometimes found, especially when the toilet of the mouth has been neglected, vegetating saprophytically on small collections of food material and epithelial detritus wherever this matter remains undisturbed. Certain conditions of the surface of the tongue, of which "hairy" tongue is an extreme example, favour the accumulation of such detritus, which is almost invariably associated with the presence of saprophytic yeasts or moulds. In course of time, but probably rarely, the saprophyte may become adapted to a semi-parasitic life and attach itself to the superficial strata of epithelium, from which its removal by mechanical means alone is no longer possible.

Local treatment by frequent swabbing or gentle brushing with fungicidal substances is necessarily experimental, but solutions of permanganate of potash, hypochlorite of soda, peroxide of hydrogen, diluted Lugol's iodine solution, or weak solutions of methyl violet or fuchsin may be tried. It would, however, be desirable before beginning treatment to determine, by microscopical examination of scrapings, that, in fact, the condition is caused by a fungus and, by isolation in culture, to identify the fungus.

Vaccination of an Allergic Subject

Q.—*A boy aged 12 years, subject to attacks of asthma and dermatitis from infancy, has not yet been vaccinated. Is there any danger in doing so?*

A.—This boy is allergic, and allergic reactions, usually in the form of rashes (erythema multiforme or morbilliforme, urticaria), may occur after vaccination. The incidence of these non-specific rashes after vaccinia is small (1: 5,000 to 1: 9,000), and they have not apparently been correlated specifically with allergic subjects; but the nature of the rash and its usual occurrence 8 to 12 days after vaccination suggest an allergic aetiology, ascribed by some workers to the small amounts of ox serum in the vaccine lymph. Another disadvantage of primary vaccination in a boy of 12 is that the reaction is likely to be severe, and post-vaccinal encephalitis, although a small risk (1:20,000 to 1:700,000), occurs most often after primary vaccination in children of school age. It would therefore seem inadvisable to vaccinate the boy unless or until he is exposed to the risk of smallpox. In such a case the multiple-pressure method would be preferable to the scratch method (see Parish, H. J., *British Medical Journal,* 1944, **2,** 781).

Adult Stammering

Q.—*Is there any possibility of complete cure of stammering in a male aged 33 with a history of frequent illnesses in childhood? Two years' service in the R.A.F. (ground staff) has greatly increased the stammer. Is treatment best undertaken by a speech therapist or by a psychiatrist, and what are the methods employed?*

A.—If the stammer has existed since childhood a complete cure is very unlikely in an adult of 33. Considerable improvement is possible; at least he should attain his pre-service level and might improve even beyond this. The fact that R.A.F. service has intensified the stammer suggests some degree of "psychoneurotic superstructure"; consequently the best line of treatment would be psychotherapy (by an appropriate psychotherapist) and also speech therapy (by a speech therapist). Speech therapists are now recognized as "medical auxiliaries," a diploma being granted to properly trained speech therapists by the recently constituted College of Speech Therapists. Psychotherapy does not necessarily mean psycho-analysis, but a modified form designed to bring about psychological readjustment as practised by many psychologists.

Pyruvic Acid

Q.—*(a) What is pyruvic acid? (b) Why is it so named? (c) Under what conditions or where in Nature is it found? (d) In what way does it neutralize the effects of vitamins B and D? (e) Is it known to have any other action? (f) Does calcium neutralize its ill effect, or is any substance known that does so?*

A.—Pyruvic acid or acetylformic acid has the formula $CH_3.CO.COOH$, and is so named because it is obtained by the action of heat (πῦρ=fire) on tartaric acid, which is found in grapes (*uva* = a bunch of grapes). It is an intermediate product of carbohydrate metabolism and is probably formed in the tissues by the anaerobic oxidation of glucose according to the following scheme: Glucose ⟶ hexose mono- and di-phosphate ⟶ phosphoglyceric acid ⟶ phosphopyruvic acid ⟶ pyruvic acid. It is found in the tissues, blood, and urine. There is no evidence that it neutralizes the effects of vitamins B and D. Vitamin B_1, however, in the form of its phosphate (cocarboxylase) catalyses the decarboxylation of pyruvic acid to methyl glyoxal, $CH_3.CHO$. A complex of protein, vitamin B_1 pyrophosphate, and magnesium also carboxylates pyruvic acid to oxalacetic acid, $HOOC.CH_2.CO.COOH$. Pyruvic acid is a product of metabolism and is not known to have any specific action. In patients with vitamin B_1 deficiency it is stated that the blood pyruvic acid is elevated, although this has been disputed. Some of the symptoms of vitamin B_1 deficiency have been ascribed to the accumulation of pyruvic acid in the body. Calcium has not been shown to have any effect on the pyruvic acid level in the body. If the latter is raised and is associated with vitamin B_1 deficiency, administration of vitamin B_1 brings the blood pyruvic acid down to normal levels. The blood pyruvic acid is also raised in insulin hypoglycaemia, hyperthyroidism, and mild diabetes.

Hydatidiform Mole

Q.—*What is the present state of knowledge of the hydatidiform mole? Textbooks seem to repeat an age-old formula. Is anything known of the aetiology? How soon after evacuation may a further pregnancy be permitted?*

A.—Hydatidiform mole is believed to be due to a developmental anomaly of the trophoblast of the young ovum. Just as such defects as anencephaly and spina bifida involve the tissues derived from the embryoblast, so does hydatidiform degeneration attack the trophoblastic tissues. The parallel may not be exact, but the principle of a developmental anomaly of the chorionic tissues holds. The cause is, of course, unknown, nor can any predisposing factors be distinguished. The morbid histology is also unsatisfactory, for there is no explanation of the method of formation of the vesicles. The proliferation of the cytotrophoblast leads to profound alterations in the endocrine balance, so that the ovaries become cystic and the excretion of chorionic gonadotrophin in the urine is greatly increased. As the fault lies in the ovum there is no objection to a subsequent pregnancy at an early date. An interval of four to six months might be suggested. There is much to be said for determining the Aschheim-Zondek reaction of the urine during the interval to exclude the development of chorion epithelioma.

Allergy to Citrus Fruit

Q.—*Last autumn and this I have frequently noticed crops of vesicles in infants and young children, on arms, legs, and sometimes the body. Attacks tend to recur over a period of weeks or months; the vesicles are usually irritable, start as red spots, then become blisters, and gradually disappear; they may reappear in a week or so; size 1/8 in. to 1/4 in.; they may become pustular. Mother and clinic usually blame oranges. What are the aetiology and treatment, and does diet or vitamin deficiency play a part in causation?*

A.—The description does not give enough detail to allow of a definite diagnosis, but the occurrence among a number of young children suggests a common factor, and if an unusual form of urticaria can be excluded, and such parasitic conditions as scabies, then it is not unreasonable to suspect oranges, because the citrus fruits are well known to cause allergic reactions of different sorts.

Occupational Cause of Leukaemia and Raynaud's Disease

Q.—*Is there a recognized occupational cause of (a) leukaemia, (b) Raynaud's disease?*

A.—Leukaemia is not generally recognized as a direct occupational disease, but it has been noted as the final phase in some cases of aplastic anaemia following exposure to benzol, and occasionally to *x* rays. A recent case of chloroleukaemia reported in a German benzol worker, for example, was considered to be related to his exposure in so far as the benzol might have had an initial aleukaemic effect followed by over-compensation of the bone marrow leading to leukaemia. (For leukaemia associated with benzol see Weil, P. E., *Bull. Mém. Soc. méd. Hôp. Paris,* 1932, **48,** 193.)

True, Raynaud's disease is not recognized as an occupational condition, but "dead hand" is known as a relatively frequent occurrence in workers using the compressed-air hammer. This is believed to be a local condition due to the concomitant action of cold (partly arising from the compressed air escaping from the tool) and of long-continued muscular contraction and transmitted vibration. (See Leys, D., *Lancet,* 1939, **2,** 692; and Desoille, H., 1937, *Ency. Méd. Chir.,* vol. 8.)

Romberg's Sign

Q.—*What is the mechanism of a positive Romberg's sign? In what conditions is it found? Where can one read Romberg's own description of this sign?*

A.—Romberg's sign is used to demonstrate a defect in the ability to maintain posture. The ability to stand upright with the eyes closed depends upon the afferent impulses from joints, tendons and muscles, and skin. Some of these impulses make the subject conscious of where his limbs are and where his body is in regard to his limbs. Some do not reach consciousness but nevertheless help in the maintenance of posture. All these impulses are co-ordinated and the resulting pattern of nervous activity maintains the postural muscles in the appropriate tonic state, through the efferent nerves. A lesion anywhere in the pathway will give rise to a defect in maintaining posture—for instance, a man with weak muscles cannot stand upright efficiently. Usually, however, the defect is in the sensory, afferent fibres, when inability to maintain posture, giving a positive Romberg's sign, is associated with loss of joint sense. The sign is therefore found in diseases where this defect occurs—for example, tabes dorsalis, disseminated sclerosis, or peripheral neuritis. Romberg's original description appeared in the *Lehrbuch der Nervenkrankheiten des Menschen* (Berlin, 1853), and a translation by E. H. Sieveking appeared in the *Transactions of the Sydenham Society,* London, 1853.

INCOME TAX

Expenses of Employment

A. S. has been employed by the Ministry of Health, it being a condition of his employment that he should attend a course of study and sit for a specified examination. Can he claim a deduction for the study and examination fees?

*** The governing rule is that an expense can be deducted if it is "incurred wholly, exclusively, and necessarily in the performance of the duties of the office or employment. The benefit to be derived from the study and the examination in question—e.g., the increase in knowledge and skill, and evidence thereof—will extend into the future, and though A. S. can presumably show that the expense was necessary in that only by complying with the condition could he continue to hold the appointment, it is, we consider, unlikely that he could establish the contention that it was incurred wholly and exclusively in the performance of the duties of his present employment. We cannot therefore advise him to appeal against the view taken by the inspector of taxes.

LETTERS, NOTES, ETC.

Oxalated Blood for Cell Counts

Dr. C. J. C. BRITTON (London, W.1) writes: The answer given under this heading in the issue of Dec. 2 (p. 744) appears incomplete. It omits to mention the very important point of the amount and type of oxalate used. The ordinary oxalate tube, as usually employed in the collection of blood for biochemical tests, contains so much oxalate that a very hypertonic fluid is inevitable, and the results found on delayed counting of such blood are grossly inaccurate, as your correspondent states. If, however, the tubes for collecting the blood are prepared in such a way as to avoid this—e.g., if they contain a mixture of exactly 4 mg. dry potassium oxalate and 6 mg. dry ammonium oxalate for each 5 c.cm. of blood taken—it will be found that the estimation of haemoglobin, the red cell count, and packed cell volume are reliable if performed within 24 hours in temperate climates, or within 2 to 3 days in cool weather. The leucocytes are much more easily damaged and destroyed, and there is commonly about 10% destruction of these cells in 24 to 36 hours. Blood films must always be made when the blood is first collected.

Growth on Ear

Dr. F. S. AIREY (Leicester) writes: I believe your inquirer would find a more precise reply of greater assistance than the one quoted by you (Nov. 25, p. 714). Chondrodermatitis nodularis chronica helicis, as first described by Winkler (painful nodule of the ear), is a clinical entity commonly encountered. The aetiology is obscure, but the lesion occurs mostly in middle-aged men (although I have seen it in a young boy) and always chooses the rim of the pinna. It is essentially a corn, being dependent upon the development of a cartilaginous outgrowth in response to intermittent pressure (perhaps from the hat brim, but more likely the pillow in bed). The visible, palpable "wart" is a nodule of fibrous connective tissue, which recurs after simple excision. Usually it is radio-insensitive. Permanent relief cannot be achieved without removal of the underlying cartilaginous spur. It is important not to limit excision to the actual nodule or a prominence will be left at each end of the arc and favour the development of secondary lesions. It is wise to strip the cartilage (not, of course, deeply) over an inch or so of the rim of the helix so as to avoid further trouble. The slight disfigurement resulting is accepted by most patients as of trivial consequence.

Insect Sprays in Sleeping Quarters

Dr. A. H. DOUTHWAITE (London, W.1) writes: With reference to your recent correspondence on the subject (Dec. 30, p. 874), it may interest your inquirer to learn of one instance in which "flit" appeared to produce toxic effects. An over-zealous housemaid had sprayed the bedroom profusely shortly before bedtime. No precaution had been taken to prevent the droplets falling on the pillows. The windows were opened just before the occupants got into bed. Both of them suffered from dreams of violent action, terrifying apparitions, and other features similar to those produced by deliriants. They awoke within an hour with headache. On changing the pillows and leaving the door open the smell of the fluid soon vanished and the rest of the night was peaceful. A year later the same train of events occurred. Other members of the household in unsprayed rooms did not suffer. On both occasions they had all eaten the same dinner. Presumably the volatile solvent was responsible.

Colt or Filly?

Dr. J. HOBART NIXON writes: Dr. L. Kilroe is correct in his doubts about Rocksand's female impersonation: the race mentioned should have been the St. Leger, not the Oaks.

Corrigenda

There was an inadvertent omission from the report of a case of locked twins received by airgraph from Dr. B. A. Bradlow of Johannesburg and printed in the *Journal* of Oct. 21, 1944 (p. 532). After the words ". . . delivered this twin as a breech presentation," the report should read: "The infant was a female weighing 5 lb. 3 oz. and only had slight blue asphyxia. He then did an internal version, turning the second foetus into a breech, and delivered it in this position. This infant was also a female, weighing 4 lb. 4 oz., and like its sister exhibited only slight blue asphyxia."

On page 57 of the *Journal* of Jan. 13, in the account of a meeting of the British Orthopaedic Association, Col. Stark (New Zealand A.M.C.) was given as one of the speakers. This should have been Col. Stout.

Disclaimer

Mr. HAROLD DODD wishes to disclaim any part in the publication in a weekly periodical of an extract from his article on varicose veins which appeared in the *Journal* of Dec. 23.

3RITISH MEDICAL JOURNAL

LONDON, SATURDAY, JANUARY 27 1945

THE ACTION OF PENICILLIN ON BACTERIA

BY

LAWRENCE P. GARROD, M.D., F.R.C.P.

Bacteriologist to St. Bartholomew's Hospital; Professor of Bacteriology in the University of London; Pathologist, E.M.S

lphonamides had been in general use for five years before nature of their action on bacteria was discovered. The tory of penicillin is developing on similar lines: so remark- le were its properties as demonstrated by *in vitro* and animal periment, and so encouraging to clinical trial, that the treat- nt of human disease was embarked on at an early stage, d has engrossed almost all attention. The far-reaching success these efforts does not diminish the need for a clearer under- nding of how penicillin acts on bacteria: such knowledge y indeed enable clinical treatment to be directed even more ectively.

In the first full description by Florey and his colleagues braham *et al.* 1941) observations on the persistent respira- n and survival of staphylococci exposed to penicillin are ntioned in support of the view that its action is bacterio- tic rather than bactericidal. By performing viable counts bacteria exposed to the action of penicillin Hobby, Meyer, d Chaffee (1942) and Rammelkamp and Keefer (1943) showed t a great diminution in the number of living cells occurs, en ending in extinction, although a small proportion of sur- ors may persist. Similar experiments by Rantz and Kirby 44) led them to state unequivocally that penicillin is bac- icidal. Bigger (1944b) has reached the same conclusion, but alifies it by advancing the hypothesis that this lethal action exerted only against bacteria which are about to divide. The ne idea has been put forward with similar supporting evi- nce by Hobby and Dawson (1944) and by Miller and Foster 44).

Up to now no author appears to have examined penicillin the methods usually applied to ordinary disinfectants. It true that penicillin is far from being ordinary, but, on the er hand, if it is a disinfectant, as some of these findings gest, an accurate knowledge of the influence on its action the various factors which are known to control chemical infection generally might well be helpful. This was the aim some of the following experiments.

Method.—The only organism used was *Staphylococcus aureus* ford H strain), of which such an amount of a 24-hour broth ure was added to the test mixture as to give a concentration of m 25,000 to about 5,000,000 viable cocci per ml. The medium ally broth), the concentration of penicillin (added as a distilled- er solution in a small volume), and the temperature were varied stated later. Survivors were counted at intervals in pour agar es from 1 in 10 to 1 in 10,000 dilutions, penicillinase made by gar's (1944) method being added if necessary.

Bactericidal Action

t has been shown by others, and is evident from the follow- experiments, that penicillin causes the death of bacteria ler favourable conditions fairly rapidly. I was not at first ined forthwith to accept this as evidence of true killing, ause bacteria kept at 37° C.—a necessary condition for the id penicillin effect—and merely prevented from multiplying, ther by a mechanism involving deprivation of nutriment or erwise, will certainly not survive long. It might appear ple to settle this point by employing a non-nutrient medium, in my hands the death rate at 37° C. of washed staphylo- ci in different batches of Ringer's solution made with s-distilled water varied inexplicably, and although usually elerated by penicillin, was once (by a different sample) clearly retarded. To distinguish between bactericidal and bacteriostatic action also demands a definition of these terms; which is to be used of a substance that inhibits an essential metabolic process and thus causes ultimate death by starvation? The distinction, in terms of effect, can only be a matter of time, and later observations have convinced me that the penicillin effect is far too rapid in some circumstances to be regarded as anything but bactericidal.

The Effect of Concentration

An increase in concentration accelerates the action of all common disinfectants. The reverse is often true of penicillin: in the experiment illustrated in Fig. 1 death was much more rapid in the presence of only 1 unit per ml. than with 1,000 units. This result is an example of those obtained in many experiments, three of which are expressed, for the sake of brevity, in a different form in the following Table. The LT50 (Withell, 1942) is the time required to kill 50% of the inoculum, and, since the survivor curve in the presence of penicillin in any given medium is of constant shape, this value fairly reflects the rate of disinfection.

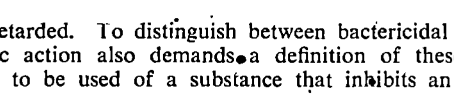

FIG. 1.—Numbers of surviving *Staph. aureus* in broth at 37° C. containing penicillin (TRC10) in concentrations of 1 unit and 1,000 units per ml.

LT50 in Minutes for 3 Different Penicillins in 4 Concentrations in Broth at 37° C.

Penicillin	Potency (Units per mg.)	Concentration of Penicillin (Units per ml.)			
		1	10	100	1,000
TRC8	30	105	111	258	195
TRC10	100	106	118	152	318
"Pure"	1,360	100	91	89	95

The first two samples were of early manufacture and contained a high proportion of impurities: both are most active in the lowest concentration—1 unit per ml.—and least active in one case in that of 1,000 units and in the other of 100. "Pure" penicillin, on the other hand (actually of about 85% purity), disinfects at an almost constant rate regardless of concentration within this range: the differences observed are within the limits of error of the method. It seems probable that above a certain necessary minimum the rate of disinfection by pure penicillin is unaffected by increase of concentration. On the other hand, something—presumably impurities—actually retards disinfection when the concentration of impure material is increased. That this does not apply only to samples of very low potency was shown by a similar experiment with a recent commercial product (Pfizer) of high potency (about 1,050 units per mg.). In concentrations of 0.1, 1, 10, 100, and 1,000 units per ml. there were less than 4% of survivors after 2 hours, but in 10,000 units per ml. there were 34%.

The effect of smaller variations in a lower range was also tested. In the following experiment each concentration is one-quarter of the preceding:

LT50 in Minutes for 2 Penicillins in 5 Concentrations in Broth at 37° C.

Penicillin	Concentration of Penicillin in Units per ml.				
	10	2·5	0·62	0·15	0·039
TRC10	92	118	118	148	>480
"Pure"	110	102	114	130	>480

There is in either case no significant difference between the rates of disinfection in the three higher concentrations: retardation is slight in 0.15 unit per ml. and marked in 0.039. A similar experiment in human blood (inactivated at 50° C. for 15 minutes), using TRC25 (360 units per mg.) in concentrations of 10, 5, 2, 1, 0.5, 0.2, and 0.1 unit per ml., gave values for LT50 of 58, 70, 75, 88, 108, 140, and 174 minutes respectively. Although these figures suggest that raising the concentration accelerates disinfection, there is less difference at a later stage: at 4 hours the percentage of survivors in all concentrations was under 3, showing that in this medium disinfection is accelerated only in its early stages by increase in concentration.

The Effect of Temperature

The action of all chemical disinfectants is accelerated by increase in temperature, and penicillin is no exception (Fig. 2).

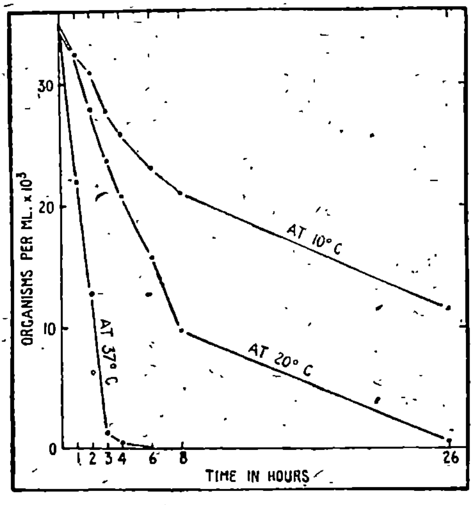

FIG. 2.—Numbers of surviving *Staph. aureus* in broth containing 10 units per ml. of penicillin at 10°, 20°, and 37° C.

The degree of this acceleration (i.e., the temperature coefficient) varies among different classes of disinfectant, and appears to be by no means so extreme for penicillin that it can be used to support the argument that this drug has a peculiar type of action. Bigger (1944b) believes that penicillin kills only dividing cells, and cites its inactivity at low temperatures in support of this; it is, in fact, slowly bactericidal not only at 10° C., as shown in Fig. 2, but at 4° C. This was demonstrated in another experiment, in which a 50% reduction in the viable count was observed in 2 days and 100% in 14. Disinfection by penicillin was also further accelerated as compared with that at 37° C. by raising the temperature to 42°. This is characteristic of an ordinary disinfectant, and not what would be expected according to Bigger's hypothesis, since at this temperature growth ceases. Further observations of the action of penici at this or even higher temperatures might be instructive.

The Effect of *p*H

Penicillin, although rapidly destroyed by strong acids, is s to be stable between *p*H 7.0 and 5.0. That it is not equ active throughout this range of acidity is shown in Fig.

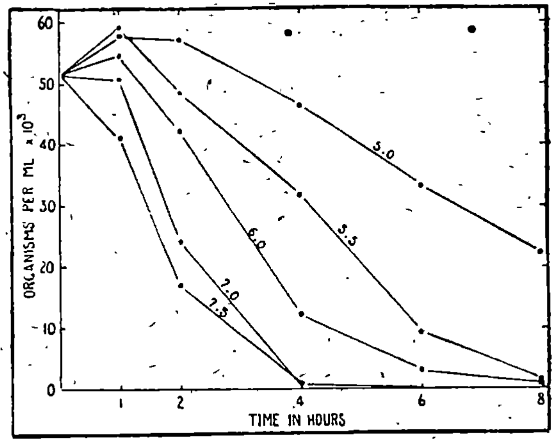

FIG. 3.—Numbers of surviving *Staph. aureus* in broth adjuste to *p*H 7.5, 7.0, 6.5, 6.0, 5.5, and 5.0, and containing 10 uni of penicillin per ml. at 37° C. (The curve at *p*H 6.5 is almo identical with that at 7.0, and is omitted. Slow multiplicatio occurred in control broth at *p*H 5.0 with no penicillin.)

which illustrates the rate of disinfection by 10 units per of penicillin in broth adjusted to six different reactions the addition of HCl (all were diluted to the same extent making up to constant volume with distilled water). T experiment was suggested by an anomalous result in an atte to confirm the observation of Abraham *et al.* (1941) that p cillin acts as well in pus as in blood, serum, or broth. pus used contained only an anaerobic streptococcus; standard staphylococcus was added to it. Disinfection pro to be much retarded relative to that in control media (br serum, and blood), and a possible cause for this was fo when the *p*H of the pus was discovered to be 5.2. A p tion was brought to 7.6 and the experiment repeated broth: at 5.2 the LT50 was still over 4 hours; at 7.6 it under 2. A low *p*H in an inflammatory exudate may th fore impair the action of penicillin: this factor is worthy study as a possible cause of failure in treatment.

The Effect of Reproductive Activity

The suggestion recently made by various authors that p cillin kills only dividing cells prompted several experime some of which support this conclusion in part, while ot do not. Their results are here stated briefly:

1. *Action in Diluted Broth.*—According to Bigger, the via count of staphylococci in 1 in 800 broth remains stationary, medium supporting life but not growth, and penicillin in medium is inactive. When the LT50 for 10 units of penici per ml. in undiluted broth at 37° C. was 103 minutes, it 208 minutes in 1 in 800 broth: the population remai stationary in a 1 in 800 broth control during this period, increased subsequently. In another experiment with a differ broth, in which very little late growth occurred, the LT50 1 in 800 medium was 335 minutes. This medium theref does reduce the rate of disinfection; it by no means prevent

2. *Presence of Another Bacteriostatic Agent.*—Bigger fo that boric acid, which is bacteriostatic, prevented the bacterici action of penicillin. I have tried two other such agents. P flavine in low concentrations is bacteriostatic for staphyloc and only slowly bactericidal. The LT50 of 1 in 90,000 p flavine in broth at 37° C. was 215 minutes, that of 10 u of penicillin per ml. 92 minutes, and that of both combi 165 minutes. Proflavine therefore does reduce the activity penicillin, but this may possibly be due to chemical inc patibility. The ideal purely bacteriostatic agent appears to a sulphonamide: the results of an identical experiment us

sulphathiazole are given in Fig. 4. Sulphathiazole in a concentration which almost completely prevents growth somewhat reduces the rate of disinfection by penicillin.

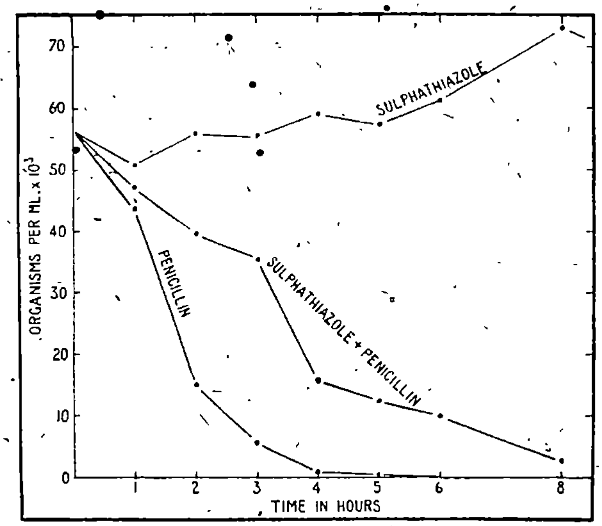

FIG. 4.—Numbers of surviving *Staph. aureus* in broth at 37° C. containing (1) 0.2% sulphathiazole; (2) 10 units penicillin per ml.; (3) both of the drugs.

3. *Age of Culture*.—If reproductive activity is an important factor there should be a marked difference in the action of penicillin on old and that on young cultures. In this there would be nothing unique: young cultures are more susceptible to disinfectants generally than old, and this is recognized in the stipulation that a culture of prescribed age shall be used for any standard test. Nevertheless it seemed worth while to study this factor, and the behaviour of a culture 10 days old (for 9 of which it had been on the bench) was compared with that of one 5 hours old (i.e., in the logarithmic phase of growth). Previous viable counts on such cultures made it possible to add approximately equal numbers of living cells from each to flasks of broth containing 5 units of penicillin per ml. at 37° C. As shown in Fig. 5, the viable count in the young culture after a slight initial rise fell rapidly; that of the old fell continuously and rather less rapidly; but the rate of disinfection is much the same in both, and lends little support to the idea that a cell is vulnerable only when dividing. Curves similar but for the absence of an initial rise in the young culture were obtained with 1 in 300 phenol controls; the greater resistance of a small proportion of old cells is clearly evident in both. Reproductive activity therefore affects susceptibility to penicillin only in the same way as it affects susceptibility to phenol.

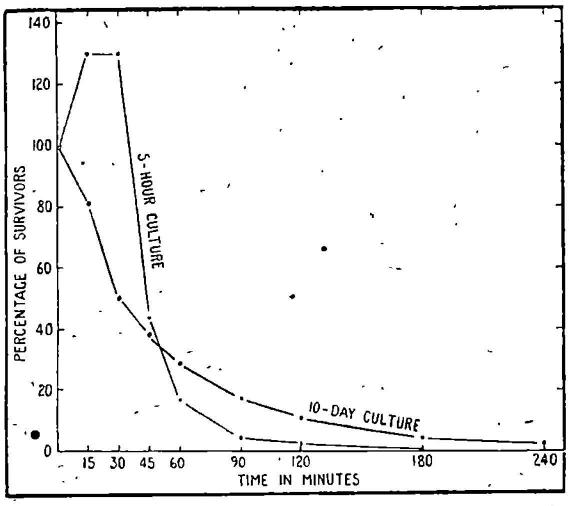

FIG. 5.—Numbers of surviving *Staph. aureus* in broth at 37° C. containing 5 units of penicillin per ml., the organism being derived from a 5-hour-old broth culture and a 10-day-old broth culture respectively.

(In this experiment the penicillin broth and the broth for diluting the cultures were brought to 37° C. before the experiment began: this doubtless accounts for the rapid death rate. In other experiments—perhaps unfortunately—the test mixtures were made at room temperature and placed in the incubator or water bath at zero time. They should have reached the required temperature within a few minutes, but Bigger's observations on the effect of cooling suggest that this brief period at a lower temperature may have unexpected effects.)

Discussion

These experiments show that penicillin is fairly rapidly lethal to susceptible bacteria. Beyond that they throw no direct light on the nature of its action. The only other lesson to be learned from them is that further studies of the intimate nature of this action must clearly be pursued with pure reagents. All commercial penicillins tested were less active in high than in low concentrations, and impurities which presumably cause this and other anomalies offer a serious obstacle to such a study. It will indeed be necessary to consider whether pure penicillin itself is a single substance of unvarying composition and uniform action.

On the other hand, some conclusions can rightly be drawn which have a bearing on the clinical use of penicillin as now available. The foremost of these is that nothing is likely to be gained by using high concentrations, particularly for local treatment. Failure of clinical response is usually considered to call for an increased dose, and there is a pardonable belief that the greater the dose the more sure the effect. True as this may be of other therapeutic agents, it is even the reverse of the truth when penicillin is concerned: a concentration of 1 unit per ml. is not only just as effective as one of 1,000 units, but often more so. The only good reason for using strong solutions in local treatment is to ensure that loss by escape, dilution, or absorption shall not permit the concentration to fall below the minimum level for full effect, which may be taken as about 0.1 unit per ml. The factors controlling this loss vary almost infinitely, from good retention in a closed space such as the theca or pleura to the impossibility of retention and the dilution by copious exudate which characterize some open wounds. The optimum strength of solution must therefore vary, but the standard probably need not exceed 250 units per ml.: this was the strength originally employed with satisfactory results for instillation into gunshot wounds after secondary suture by Florey and others in North Africa. That this policy has an additional advantage in economy needs no emphasis.

These experiments also have some practical bearing in relation to Bigger's proposal that systemic penicillin treatment should be intermittent. His argument is that penicillin kills only dividing cells, and that a very small proportion of dormant non-dividing cells which he terms "persisters" are liable to survive: these must be permitted to grow by interrupting treatment if sterilization is to be complete. Of the experiments described here, those using diluted broth and combinations of penicillin with bacteriostatic agents give some support to the idea of a special action on dividing cells. It should be observed in this connexion that Bigger (1944a) has previously recommended combined treatment with sulphathiazole and penicillin: if, as it appears, the action of sulphathiazole as a bacteriostatic agent interferes with that of penicillin, it must detract from rather than add to therapeutic effect. His two ideas of synergic action and bacteriostatic interference are in fact plainly incompatible.

On the other hand, studies of the effect of temperature and particularly of reproductive activity on susceptibility to penicillin demonstrate behaviour which seems to differ in no qualitative sense from that of other disinfectants. While much remains unknown or doubtful, I submit that the evidence for Bigger's hypothesis is inadequate to support so drastic a change in therapeutic policy as he advocates. Clinical experience supports this attitude; the reason for therapeutic failure is to be found not in any property of the micro-organism but in the morbid anatomy of the lesion. Treatment fails in patients with inaccessible foci of infection, such as an area of necrosis in bone, an endocardial vegetation, or an undetected abscess: even those with the severest infections but without such foci regularly recover.

Summary

Penicillin has a bactericidal action.

This action proceeds at a constant rate regardless of concentration within wide limits if pure penicillin is used: impure samples are more effective in low than in high concentrations.

This action is accelerated by increase in temperature throughout the range 4° to 42° C.

The action of penicillin is progressively impaired by an increase in the acidity of the medium between *p*H 7.0 and 5.0.

The behaviour of penicillin in diluted broth and in the presence of bacteriostatic agents supports the hypothesis that it acts only on dividing cells; the effect of temperature and the almost uniform susceptibility of cells from both old and very young cultures are against it.

I am indebted to the Penicillin Clinical Trials Committee of the Medical Research Council for most of the penicillin used, and to I.C.I. (Pharmaceuticals) Ltd. for the gift of 183 mg. of nearly pure penicillin. This work could not have been done without the assiduous technical assistance which was given by Miss P. M. Waterworth. For her services and for the equipment of the laboratory in which the work was done I am indebted to a fund, under the control of Mr. Rainsford Mowlem, which was generously provided by the United States organization "Bundles for Britain."

PENICILLIN IN GONORRHOEA AND SYPHILIS

WITH NOTES ON TWO CASES OF DUAL INFECTION

BY

F. L. LYDON, M.B., B.Ch.

Major, R.A.M.C.; Specialist in Venereology

AND

W. R. SCOTT COWE, M.B., Ch.B.

Capt., R.A.M.C.; Graded Venereologist

Middle East Forces

In recent years the widespread use of the sulphonamide group of drugs in the treatment of venereal diseases has had fairly satisfactory results. These drugs have been employed successfully in the treatment of gonorrhoea, soft sore, and other types of non-specific genital ulceration, and lymphogranuloma inguinale. However, from the clinical point of view certain difficulties were early encountered. These were due to the simple fact that a patient presenting the appearances of one venereal disease may well be incubating one or more of the others. Sulphanilamide itself, while almost uniformly successful in clearing an uncomplicated Ducrey infection, is not nearly so effective in the treatment of gonorrhoea. In fact, many cases of the latter infection treated with sulphanilamide developed afterwards a persistent mucoid or muco-purulent discharge due to such complications as anterior folliculitis or a posterior spread. Later a similar effect was seen in certain cases treated with inadequate or "self-administered" doses of sulphapyridine. These cases were extremely difficult to clear up and required prolonged hospital treatment.

The incubation periods of chancroid and gonorrhoea are roughly the same, and in addition a patient may have had more than one recent exposure to infection. Thus a man admitted to hospital a few days after his last exposure to infection and presenting a clinical chancroid might at the same time be incubating gonorrhoea. It became obvious, then, that in such a case the administration of sulphanilamide, while clearing the Ducrey infection, would in all probability mask the signs of the incubating gonorrhoea. In the early days this not infrequently happened. The patient was discharged from hospital with a healed sore and returned in a week or ten days with a persistent urethral discharge showing many pus cells, some secondary organisms, but no gonococci. There was no history of further exposure to infection. This type of case was peculiarly resistant to treatment, and generally one or other of the commoner complications of gonorrhoea was found. This difficulty was obviated by a routine which forbade the use of sulphanilamide in "sore cases" until at least 14 days after the last admitted exposure to infection.

These facts, when realized, are in the main a matter of clinical interest and do not present any serious problem or administrative difficulty. They serve, however, as an introduction to the theme of this short article, which is intended to point out the similar but much more serious difficulties at present attendant on the treatment of sulphapyridine-resistant gonorrhoea with penicillin.

Penicillin is now coming into general use in the treatment of resistant gonorrhoea cases, in which it has been found almost uniformly successful. In the first place, then, it will not be remiss to discuss what we know of its effect on the spirochaete of syphilis, more particularly as many—one might even say most—of the gonorrhoea cases so far treated have been within the incubation period of syphilis—that is, less than three months after the last exposure to infection.

The first observation to be made is on the report from the U.S.A. on 50 cases of early syphilis treated with penicillin, the dose used being 2,500,000 units. The details are not available here. So far as can be gathered, however, *Treponema pallidum* disappeared early from primary lesions, which healed rapidly, and the blood has remained Wassermann-negative for the present period of observation; while in early sero-positive cases there was a gradual reversal of the blood Wassermann to negative. This is as far as the story goes. It is a hopeful report, but we have no means of assessing what will be the ultimate outcome of these cases—i.e., whether this dosage is curative. In this connexion it would be well to remember that penicillin administered intramuscularly or intravenously does not pass into the spinal fluid unless perhaps in minute quantity. Therefore, since invasion of the central nervous system by *T. pallidum* is common in early syphilis, one consideration of vital importance is the possibility that C.N.S. involvement may show an increased incidence.

The second observation is on two cases of sulpha-resistant gonorrhoea recently under our care.

Case I

Pte. X. entered hospital on Sept. 11, 1944. Definite dates of exposure to infection were difficult to obtain accurately (language difficulty). Though he said that the last exposure was approximately seven weeks before admission, the clinical findings suggested a more recent one.

On examination the patient was found to have a purulent urethral discharge and a clinical syphilitic chancre in the coronal sulcus. He stated that the sore had been present for four weeks and the urethral discharge for a shorter period. A urethral smear showed many intracellular gonococci, and the urine was hazy in both glasses. Dark-ground examination showed the sore to be positive to *T. pallidum*. Routine sulphapyridine—27 g. over 5 days—was given, and anti-syphilitic treatment was withheld until the course was completed. A blood Kahn test on Sept. 12 was negative. On Sept. 19 a urethral smear still showed intracellular gonococci, and there was a muco-purulent urethral discharge with hazy urine in both glasses. On dark-ground examination the sore was again positive to *T. pallidum*. It was therefore decided to start penicillin treatment for the gonorrhoea and use the opportunity offered to observe the action of this drug on the primary syphilitic lesion.

On Sept. 19, 100,000 units of penicillin were administered intramuscularly in doses of 20,000 units three-hourly. Dark-ground examination of the sore was carried out before each injection of penicillin. The following observations were made: (1) The sore was positive to *T. pallidum* before the first, second, and third injections of penicillin but was negative thereafter—that is, after 60,000 units (2) A mild general reaction was noted and the temperature rose to 100° F. six hours after the first injection. This reaction corresponded in time to the usual Herxheimer reaction found after initial arsenic in a primary case. Twenty other patients treated with the same batch of penicillin had no reaction. (3) The next day—Sept. 20—the sore was still negative to *T. pallidum* and considerably cleaner Urethral discharge had ceased, and urine was clear in both glasses (4) Daily examination showed the sore to be negative to *T. pallidum* on each succeeding day until Oct. 3—i.e., 14 days after starting penicillin treatment, and at this time had almost completely healed. (Only saline dressings had been applied.) (5) The following Wassermann and Kahn results were obtained at two different laboratories:—Lab. A: Kahn test negative on Sept. 21, 24, 29, and

Oct. 5. Lab. B: W.R. double positive, Kahn positive on Sept. 26 (W.R. + + ; K.T. +); W.R. and Kahn both negative on Oct. 5.

At this stage it was considered unjustifiable to withhold routine eatment with arsenic and bismuth. This was started on Oct. 5, nd it was interesting to note that after the first 0.3 g. of N.A.B. there was mild general malaise and the temperature rose to 99° F. urther treatment has been uneventful. Kahn tests on Oct. 9 and 18 were both negative.

Comment.—Although the date of exposure to infection is not bsolutely definite the expectation in this case would be that blood W.R. and Kahn tests would have been positive before routine treatment was instituted. A weak positive was obtained in one laboratory, but repeated controls at this and the other laboratory were all negative. Depending on the sensitivity of the antigen, this probably indicates that the penicillin had prevented an impending positive erum reaction.

Case II

Gnr. Y. was admitted to hospital on Aug. 28, 1944, with the ollowing history: exposure to infection two weeks and three months previously; treated for fresh gonorrhoea with 27 g. of sulphapyridine n M.I. room from Aug. 21 to 28: urethral discharge persisted.

On admission he had a purulent urethral discharge with some edema and induration in the region of the fraenum. Clinically his latter condition was suggestive of an intra-urethral chancre. A blood Kahn test on Aug. 28 was negative. A further course of ulphapyridine was given from Sept. 2 to 6. A urethral smear on ept. 11 and succeeding days still showed intracellular gonococci, and the urine was hazy in both glasses. Perifraenal oedema and nduration persisted, but over the period Sept. 2 to 14 nine dark-ground examinations of the urethral discharge were negative to . *pallidum* despite the clinical appearances.

In view of the sulphapyridine-resistant gonorrhoea 100,000 units of penicillin were given on Sept. 18. A urethral smear on Sept. 20 howed no gonococci, but a slight watery discharge persisted until Oct. 2. Daily dark-ground examination of this was negative to . *pallidum*.

He was discharged from hospital on Oct. 5. There was no urethral discharge, and the urine was clear in both glasses. The oedema and induration around the fraenal region had slowly subsided after penicillin therapy and had disappeared by the time the patient left he hospital.

Comment.—Although oedema as described above is occasionally present in acute gonorrhoea it usually does not persist so long even n sulpha-resistant cases. It is felt, then, that in all probability this was a case of intra-urethral chancre despite negative dark-ground ndings. In view of this and the findings in Case I it is intended o prolong the period of post-hospital surveillance in this case, egular blood tests being carried out over a period of two years.

Discussion

The present dosage of penicillin used in the treatment of esistant gonorrhoea is 100,000 units, and a group of cases was ecently reported in which 60,000 units were found adequate. hese dosages, then, according to the presumptive evidence of eports on the treatment of syphilis, are quite inadequate to ure this disease, but on our own observations are perfectly dequate to effect the clinical cure of a primary lesion in itself. Obviously they will also very successfully mask any primary esion which a patient with gonorrhoea may be incubating.

The following problems now arise: (1) What interval must lapse before such an inadequately treated case will develop positive blood W.R. or systemic manifestations of syphilis? 2) On the analogy that an early syphilis inadequately treated with the arsenicals frequently develops precocious tertiary esions, will this also hold true of penicillin? (3) On the ame analogy, is not such a patient likely to remain infective during the assumed latent period? At present we have no vidence on these points.

What, then, is to be the routine in cases of sulpha-resistant gonorrhoea treated with penicillin? We know that a certain mall but definite percentage of gonorrhoea cases are incubating yphilis, which may not show until the final blood test after hree months' surveillance. The reasonable assumption now is that with the advent of penicillin these cases will be completely masked, according to the observations on the two cases quoted. Two alternatives appear to be open. Either the initial dosage must be sufficient to deal with a possible coexisting yphilis (2,500,000 units) or surveillance must be extended to over a period of (say) two years after treatment to exclude he latent systemic spread of any possible coexisting syphilis o which the patient is exposed on the present routine. In our present state of knowledge the first is obviously wasteful. The second appears to be the only fair method, not only to the patient himself but also to the community in general.

Having reviewed briefly the probable effect of penicillin in masking an early syphilis it would be well at this stage to think of the numerous patients who have had penicillin treatment for general infections. Large numbers of these have been battle casualties with heavily infected wounds. With our knowledge of conditions in the various theatres of war it is reasonable to assume that any one of these cases may have been incubating syphilis at the time penicillin treatment was instituted, and the dose, though large, may not have been the postulated curative dose. Will the patient's signs and symptoms too be masked until in a few years' time the poor unfortunate begins at an early age to suffer from anginal pain or his wife gives birth to a snuffling child?

This article is not intended to be destructive or pessimistic, however much it may appear so. Penicillin has more than proved its value as a life-saving measure and in many acute and chronic infections which previously would have led to marked general debility and prolonged hospitalization. To the venereologist it is the drug of choice in the treatment of gonorrhoea. There is no doubt that as further supplies become available it will, and must, be even more extensively used.

However, it is hoped that enough has been said here to emphasize the need for the most careful and prolonged surveillance of penicillin-treated gonorrhoea cases (and even in cases where venereal disease might be suspected in a patient treated for some other condition) until our present knowledge of the effect of the drug in syphilis is much further advanced.

Regarding the second group of cases mentioned, it cannot be too strongly advocated that, in future, routine blood tests of the whole population should be enforced by law, particularly before marriage.

Conclusion

By force of circumstances this article has been largely theoretical and referable to a very small percentage of cases. However, until we know in detail the response of early syphilis to small doses of penicillin both from the clinical point of view and from that of change in the serum reaction, the necessity for very careful assessment and prolonged surveillance of every case would appear obvious, particularly in view of the two cases described.

THE TEMPORARY CHARACTER OF "FASTNESS" OF STAPHYLOCOCCI TO PENICILLIN

BY

E. W. TODD, M.D., D.P.H.
G. S. TURNER, A.I.M.L.T.
AND
L. G. W. DREW

(From the Inoculation Department, St. Mary's Hospital, and the Serum Institute, Wellcome Foundation, Carshalton, Surrey)*

It is generally assumed that micro-organisms which have been made resistant to bacteriostatic drugs or to antibiotic agents by continued subcultivation in increasing quantities of the antibacterial substance will remain "fast" after many subcultures in ordinary laboratory media. Fleming and Allison (1927) showed that *Micrococcus lysodeikticus* could be made resistant to lysozyme, and that after repeated subcultures extending over nine months in ordinary culture media this resistance was fully maintained. Similarly, bacterial resistance to sulphonamide drugs appears to be a permanent characteristic. McLeod and Daddi (1939) found that a "sulphapyridine-fast" strain of pneumococcus Type I remained resistant after 30 subcultures in broth.

Rake *et al.* (1944) subcultured pneumococcus Type III in penicillin 55 times, thereby raising the bacteriostatic dose of penicillin from 0.03 unit to 0.95 unit. After 32 subcultures of their resistant strain in ordinary blood broth the bacteriostatic dose of penicillin remained unchanged. Schmidt and Sesler (1943) made pneumococci resistant by passages through penicillin-treated mice; they then passed their resistant strain through 30 normal mice without any loss of resistance.

---

* Seconded for the duration of the war from the London County Council.

Spink *et al.* (1944) found that staphylococci which they had made resistant by 109 transfers in penicillin *in vitro* showed no loss of resistance after storage on veal-agar for three months in the refrigerator.

Methods

In the following experiments 100 c.cm. of broth was infected with 0.25 c.cm. of a broth culture of staphylococcus. A suitable dilution of penicillin was added to a portion of this infected broth, and a series of tubes was then set up containing the infected broth with falling dilutions of penicillin on a 20% range in a total volume of 1 c.cm. After 24 hours' incubation the last tube showing no growth was noted, and 0.25 c.cm. from the next tube, in which the staphylococci had grown out, was subcultured into 100 c.cm. of broth for the next test. This process was continued daily until the culture was highly resistant to penicillin; it was then subcultured daily in ordinary broth without any penicillin, and titrations were done at frequent intervals to determine the resistance of the strain to penicillin.

Staphylococcus Strain "Oxford H"

This is the standard strain of staphylococcus used for the assay of penicillin. Fig. 1 shows the results of subculture in penicillin and of subsequent subculture in ordinary broth. At the beginning of the experiment 0.06 unit of penicillin was sufficient to cause bacteriostasis. After 11 subcultures in penicillin 2 units were required to cause bacteriostasis. During the next two subcultures the maximum quantities of penicillin used—namely, 4 units and 10 units—failed to cause bacteriostasis, and at the fourteenth subculture 40 units of penicillin were required for bacteriostasis. After 27 subcultures the resistant staphylococci grew in 160 units but not in 200 units, and had therefore become 3,000 times more resistant to penicillin than the original culture. As noted by previous workers, the character of growth in broth and on agar had changed with increasing resistance. Growth in broth was comparatively scanty, and various colony forms were seen on solid media. Rake *et al.* found that three colony forms of their resistant strain varied in their degree of resistance to penicillin, those with the greatest morphological variation from the parent strain showing the greatest increase in resistance.

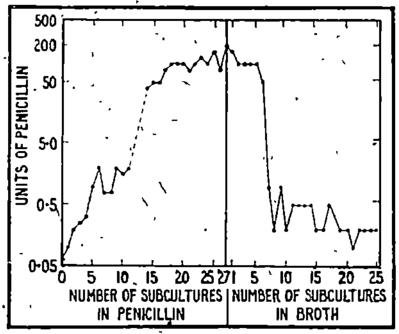

FIG. 1.—Showing increasing resistance on subculture in penicillin followed by diminishing resistance on subculture in broth. Staphylococcus "Oxford H."

The highly resistant strain was now subcultured daily in tryptic digest broth without any penicillin, and the opacity of each subculture was noted by comparison with barium sulphate standards. During the first three subcultures the opacity was less than 1. After six subcultures, when the cocci grew in 50 units of penicillin but not in 100 units, the opacity had returned to normal, giving readings between 2 and 3, and it remained at this level until the end of the experiment. There was then a rapid fall in resistance to penicillin, and after 19 subcultures the cocci grew in 0.1 unit but not in 0.2 unit. The resistance to penicillin had therefore fallen in 19 subcultures from 3,000 times to little more than twice the original level. After 36 subcultures the bacteriostatic dose was 0.12 unit, and for the original untreated culture it was still 0.06 unit.

Slight variations in resistance to penicillin can be obtained without any exposure to penicillin. The "Oxford H" strain was found to grow in 0.05 unit of penicillin but not in 0.06 unit. It was then subcultured daily for about a month in horseflesh-infusion broth containing 2% of proteose peptone and in tryptic digest broth. The two cultures were then retested, and it was found that the infusion-broth culture still had a bacteriostatic dose of 0.06 unit, while the digest-broth culture had a bacteriostatic dose of 0.03 unit.

A resistant strain of "Oxford H" which had been subcultured 40 times in penicillin grew in 250 units but not in 300 units. After 21 subcultures in infusion broth it grew in 0.16 unit but not in 0.2 unit. When a highly resistant strain of staphylococcus "Oxford H" was subcultured on agar the fall in resistance was slower and less complete. A strain which grew in 320 units of penicillin per c.cm. but not in 400 units was subcultured daily on agar slopes. After 28 subcultures the cocci grew in 0.5 unit of penicillin per c.cm but not in 0.6 unit.

Staphylococcus Strain "A"

Fig. 2 shows the results of a similar experiment with a different strain of staphylococcus. The original bacteriostatic dose of penicillin for this strain was 0.08 unit. After 21 subcultures in penicillin the bacteriostatic dose was 20 units, and after 10 subcultures in broth the organisms grew in 0.2 unit but not in 0.5 unit. After 36 subcultures the bacteriostatic dose was 0.2 unit, while the untreated culture grew in 0.06 unit but not in 0.08 unit. With this strain the bacteriostatic dose was increased 250 times by subcultivation in penicillin, and on transfer to broth it rapidly fell again to less than three times the dose required to inhibit the untreated culture. The first four subcultures in broth had an opacity of less than 1, the next four had opacities between 1 and 2, and subsequent subcultures were between 2 and 3. As in the previous experiment the cultures remained coagulase-positive throughout.

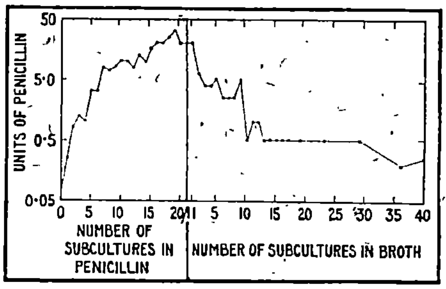

FIG. 2.—Showing increasing resistance on subculture in penicillin followed by diminishing resistance on subculture in broth. Staphylococcus strain "A."

Discussion

It appears from these experiments that staphylococci which have become highly resistant to penicillin after subcultivation in increasing concentrations of the drug *in vitro* lose their resistance to such an extent on subcultivation in broth that they become sensitive to penicillin in concentrations which are easily attained in the human body. It does not seem unreasonable to suppose that staphylococci which have become resistant to penicillin *in vivo* might similarly revert to the penicillin-sensitive state on withdrawal of the drug. Indeed, it seems possible that the reversion might be more rapid *in vivo* than *in vitro*, since Spink *et al.* have shown that penicillin-resistant staphylococci are much more susceptible to the bactericidal action of human blood than normal staphylococci which are sensitive to penicillin.

It seems to be a general rule that organisms which have become "fast" remain in that condition for an unlimited number of generations, and it is well known that organisms such as *Streptococcus pyogenes* and *Gonococcus* which have become resistant to the sulphonamides retain their resistance to the drug through many generations, and that cross-infections with these resistant strains breed true. Organisms other than staphylococci have not been tested in the present work, but Rake *et al.* have shown that pneumococci retain their resistance penicillin on subcultivation in laboratory media. It may be at penicillin-resistant staphylococci are an exception to the neral rule, and that, consequently, resistant strains of this ganism will not appear in clinical practice after more olonged use of the drug.

Summary

Two strains of coagulase-positive staphylococci were made peni- llin-“fast” by cultivation in increasing quantities of penicillin. ey were then subcultured daily in broth without penicillin and, ntrary to expectations, a rapid fall in resistance to penicillin was ted. It therefore appears that “fastness” of staphylococci to nicillin is not a permanent characteristic.

WEIL'S DISEASE IN NORMANDY: ITS TREATMENT WITH PENICILLIN

BY

ERNEST BULMER, O.B.E., M.D., F.R.C.P.
Brigadier; Consulting Physician, 21 Army Group; Honorary Physician, Birmingham Hospitals

view of the experiences of the last war Weil's disease was ot unforeseen in the present campaign in North-West Europe. oradic cases have occurred, and the opportunity has been ized of treating cases with penicillin. Such results as have een obtained are presented now, as no further cases have been en for over two months.

History of Outbreak

Weil's disease is spread by infected rats who pass the spiro- aetes in their urine; the organisms can live for some time stagnant streams, in wells, and in the zoogloea-like substance n the walls of wells and sewers. It has been impossible to ake detailed studies of the epidemiology of the disease, nor re these necessary. The source of the infection was almost rtainly water which men used for washing. Drinking-water as supplied from water-carts or was sterilized in some way, ut the supply was not sufficient for other uses; the men were orced to draw water from wells or streams for washing, aving, and brushing their teeth. They bathed when they ould in any available stream. On some sectors they lived damp rat-infested ditches. As cases were few it was decided at the risk was worth taking, as the alternative—even if it ould have been enforced—would have been that the men emained dirty or unrefreshed by bathing during the dreary nd often very hot period on the Normandy beach-head.

Up to date (December, 1944) cases have been met with only Normandy, and only from the middle of July to the end of eptember. It is surprising that conditions in the Low Countries ave not produced further infections: there is plenty of water, oth in canals and in the fields, but the weather has been nattractive for the bather, and organized bathing and ablution cilities are much better. I saw the first recognized case on ly 18 with Major C. L. Davidson in a C.C.S. near Caen. The atient had had a febrile illness with severe muscle pains and a ucocytosis; on the tenth day he had a very faint icteric tint his conjunctivae, but was convalescent. We discussed the ossibility of Weil's disease, and a few days later we learnt at the agglutination test was positive. The beach-head was small then that it was easy to tell all the physicians at .C.S.s and hospitals to watch for it: its presence made com- on or garden jaundice an attractive clinical problem. Cases ropped up in many units, and when the outbreak ceased at e end of September I had been informed of 39. It is difficult compute the extent of the outbreak; my figures must be complete, and cases must have been missed, especially those ithout jaundice. Of the 39 cases only two did not have undice, whereas the number should have equalled those with undice. I would make an informed guess that about 100 ases occurred altogether.

Some cases were very severe, and supplies of antileptospiral serum at first were scanty; it seemed possible that the leptospira might be penicillin-sensitive, and Col. J. S. K. Boyd, Deputy Director of Pathology, ascertained in a telephone conversation with the War Office that it was moderately sensitive. It was at once decided to investigate the matter. In only one case—the only fatality in the penicillin series—was antileptospiral serum given.

Clinical Features

These will not be recited at length—they are well dealt with in the standard textbooks. Those of us who were little familiar with the disease were struck by its unusual features: a brisk febrile illness with severe muscle pains as the leading symptoms, associated with a leucocytosis and complicated by signs of gross renal damage. In the presence of an outbreak this picture is highly suggestive even if jaundice does not follow. In all but two of our cases jaundice developed on or after the fifth day; in sharp contrast to “infective hepatitis,” the temperature did not subside when jaundice appeared; it usually increased, and the urine still showed the signs of renal damage. In most cases there was some haemorrhagic incident—conjunctival ecchymosis, epistaxis, haemoptysis, haematemesis, purpura.

The disease if at all severe ran a longish course, the temperature was maintained for perhaps two weeks, and there were often febrile relapses later. The patients were very debilitated, but as they could not remain in the theatre of war we did not find out how long convalescence was going to take, or whether some would develop a type of cirrhosis within a few months.

Of the special types described the anginal form was rare; there were three examples of the meningeal form, but only one had an abnormal cerebrospinal fluid; lung involvement with haemoptysis, watery sputum, and abnormal signs, both physical and radiological, was not uncommon.

Laboratory Findings.—Spirochaetes were found in the blood in several cases, and in the urine in quite a number—both by dark-ground illumination. Animal inoculation was possible only when a resourceful pathologist was able to procure a guinea-pig by local purchase. In most of the cases positive agglutination tests were obtained by sending blood to the U.K. I am satisfied that the errors in diagnosis of Weil's disease have been negligible.

Penicillin Treatment

The dosage recommended was 40,000 units 3-hourly, with a total of about a million units. The average amount given was 1,125,000 units—some by continuous intramuscular drip, some by intramuscular injection—and there was a certain variation in dosage.

Our difficulties in assessing the results have been great. The disease rapidly inflicts severe damage on liver and kidneys, and to be successful any treatment must be given early enough to anticipate this; in practice this means that treatment must be started before the diagnosis has been firmly established—perhaps at a time when a diagnosis is impossible to make. We were dealing with a disease with which few of us were familiar, and no case was treated in the pre-icteric stage when there was the best chance of rapid resolution. Even if penicillin should prove to be a specific remedy it seems doubtful how often really early treatment will be practicable, unless there is so big an epidemic that everyone becomes very skilled in early diagnosis.

We have been unable to find any satisfactory measurement of progress. The numbers we had were too small to warrant any statistical approach—I have avoided any deduction from the deaths occurring in the treated and the untreated. With an elaborate laboratory service it might be possible to estimate the rate of disappearance of spirochaetes from blood or urine—this would need experimental animals, which we lacked. The most promising indication of progress was the effect of the drug on the temperature and on the number of febrile relapses. As is only too common in medicine, we were left with a clinical impression; this demands a nicety of judgment and an intellectual honesty which the observer may indeed possess but which a critic could be forgiven for doubting.

Most of the severe cases received penicillin and recovered; all observers claimed a dramatic improvement in 36 hours, which was usually reflected in the temperature chart, but with slow improvement in jaundice and urine. Of the fatal cases, I doubt whether any treatment would have saved the two who died of suppression of urine (one treated, one not treated); the third case was not thought severe enough to need penicillin, and this patient died of auricular flutter on the 21st day: this should have been averted if there had been a specific treatment.

Lieut.-Col. L. H. Howells and Major R. R. Hughes made an intensive study of seven cases, six of which they treated with penicillin. Their conclusions were as follows:

1. Penicillin in adequate doses appeared to shorten the general effects of the disease as assessed by the duration of the fever; it had an effect on the number of febrile relapses, and these results bore a direct relation to the dosage.
2. Penicillin did not seem to influence the degree and duration of the cholaemia as estimated by the icteric index and the van den Bergh test, or to affect the rate of disappearance of icterus from the skin or of bile from the urine.
3. Penicillin did not influence the degree of nitrogen retention as estimated by the blood urea, or the degree or rate of disappearance of albuminuria.
4. Apart from the objective evidence mentioned in paragraph 1 there remains only the very definite clinical impression that cases treated with penicillin, especially with high doses, improved dramatically within 36 hours.
5. It is considered that penicillin should be given in cases of Weil's disease as soon as possible and in high doses. Once liver and kidney damage has occurred penicillin does not appear to minimize the results of this; hence it would be interesting to observe the effects of the drug during the pre-icteric phase.

Results

The results in the present series of cases of Weil's disease are as follows:

Total cases	39
Penicillin-treated	16
8 severe, 7 moderate, 1 mild. (14 confirmed by agglutination tests.) 1 died of uraemia	
Untreated	23
2 died—1 of myocarditis on 21st day, 1 of uraemia soon after admission	

Discussion

I have presented the results of the treatment with penicillin of 16 cases of Weil's disease. It would appear that there has been an effect on the speed with which the temperature falls and on the number of febrile relapses, while all the observers claimed an improvement in the patients' general condition within 36 hours. These are scanty pieces of evidence on which to base definite conclusions.

In another theatre of war penicillin treatment, in my opinion, has been considered as ineffectual, but the dosage used was inadequate—15,000 units 3-hourly. It is known that certain strains of leptospira are penicillin-sensitive *in vitro*.

In view of these facts it is felt that further work on this subject should be pursued; it is essential to give treatment early, and the dosage should be high.

I have followed this work throughout, and have seen most of the patients; nevertheless my part in this paper is that of compiler on behalf of the following physicians of 21 Army Group: Lieut.-Cols. C. L. Cope, G. G. Gillam, L. H. Howells, R. L. Mackay, I. McGolrick, I. Murray, R. E. Tunbridge—all R.A.M.C.; Lieut.-Col. J. H. Geddes, R.C.A.M.C.; and Majors H. A. Dewar, R. R. Hughes, S. B. Karani, and Capt. J. A. Lorimer—all R.A.M.C.

More than 250 hospitals in England and Wales are now using rehabilitation methods—including physiotherapy, remedial exercises, outdoor games, and handicrafts. This is nearly twice as many as a year ago, when the Ministry of Health made a special appeal to civilian hospitals to establish a rehabilitation department as soon as possible. Some hospitals are using local halls; others have been supplied by the Ministry of Health with prefabricated huts for remedial exercises and other activities. The Ministry also lends equipment for gymnastics, sports, and occupational therapy. The majority of some 400 hospitals covered by a Ministry of Health survey have appointed a member of the staff as a rehabilitation medical officer. Many of these doctors have attended special courses at selected rehabilitation centres. Other courses have been provided for physiotherapists, handicraft teachers, and others. To help with the resettlement of disabled persons in industry, large firms in the neighbourhood of certain hospitals have established special workshops in which disabled employees may be restored to working capacity by exercising the affected limbs in suitably adapted work under proper supervision.

LOCAL PENICILLIN THERAPY IN OPHTHALMIA NEONATORUM*

BY

ARNOLD SORSBY, M.D., F.R.C.S.

AND

ELIZABETH HOFFA, L.R.C.P.&S.Ed., D.C.H.

Unlike the sulphonamides, penicillin remains effective in t presence of pus. It therefore has possibilities for the loc therapy of ophthalmia neonatorum as an alternative to gene sulphonamide treatment of this affection. To investigate t possibility 47 infants at the Ophthalmia Neonatorum Unit White Oak (L.C.C.) Hospital were treated with penicilli Table I brings out the salient features in summary form.

TABLE I.—*Showing results in 47 Cases of Ophthalmia Neonatoru Treated by Various Concentrations of Penicillin. (+ = Successful Treatment; − = Failure)*

Organisms	Concentration of Penicillin: Oxford Units per c.cm.							
	500		1,000		1,500		2,500

* Including one case which relapsed.
† Relapsed after clinical cure in 6 days.
‡ Both initially clear after 8 days and 4 days respectively when relapse occurr

The Series as a Whole.

(*a*) Initially, penicillin was used in a concentration of 5 Oxford units per c.cm. Eight cases received this treatme one drop of the solution being instilled hourly during the fi 24 hours, and continued two-hourly subsequently. Only thr of these eight cases were cured. Two more showed an init recovery, which, however, was not maintained. The thr cured cases required treatment for 2 days, 3 days, and 6 da respectively.

(*b*) A second series of 7 cases were treated with penicill in a concentration of 1,000 units per c.cm., the method application in three cases being as in the first series, and the remaining four cases the penicillin was instilled at ha hourly intervals for 24 hours and hourly subsequently. Fo of this series of 7 cases showed clinical cure in 2, 4, 2, a 5 days respectively; one case did not respond to treatmen while the remaining two cases both relapsed after an initi recovery.

(*c*) A further 10 cases constituted a third series treated wi penicillin, this time in a concentration of 1,500 units per c.c (the drops being instilled half-hourly during the first 24 hou and hourly subsequently). Six of these 10 cases showed excellent response, clinical cure being obtained in 18 hou in one case, in 2 days in four cases, and in 3 days in t remaining case successfully treated. Two cases showed a po response in spite of treatment for 4½ and 5 days respectivel in one case penicillin treatment was discontinued after 3 da as progress appeared inadequate; in the remaining case this series an initially satisfactory response which gave a cli cal cure within 2 days was followed by a relapse which d not respond to further penicillin therapy.

(*d*) Twenty-two infants were treated with penicillin in concentration of 2,500 units per c.cm., the drops being instill half-hourly for the first 3 hours, then hourly for 24 hours a two-hourly subsequently. In all but one case there was excellent clinical response, recovery in some instances being a matter of a few hours, as can be seen from the following summary:

---

* A report to the Penicillin Trials Committee of the Medic Research Council.

Time taken for a Clinical Cure		Number of Cases	
3 hours	3–24 hours	1	6
7 "		1	
12 "		2	
18 "		1	
24 "		1	
27 "	27–43 hours	1	7
36 "		1	
37 "		1	
40 "		3	
43 "		1	
50 "	50–100 hours	1	7
60 "		1	
70 "		1	
78 "		1	
100 "		3	

One case is omitted from this table, as the complication of corneal ulcer—present on admission—delayed a return to normal.

One point deserves stressing. Rapidity of clinical cure does not seem to depend altogether on initial mildness of the condition. Of these 20 cases, 4 were severe; they cleared up in 36, 40, 40, and 37 hours respectively, while all the 7 cases that required 50 to 100 hours were either mild or moderate.

Differential Susceptibility of the Causal Organisms to Penicillin

Of the 25 cases in the first three series only 13 showed clinical cure, 5 more relapsed after apparent clinical cure, and 7 gave a poor response or none at all. The distribution of organisms in these different cases is summarized in Table II.

TABLE II

Organisms	Number showing		
	Clinical Cure	No Result	Relapse after Apparent Cure
Gonococci	6	3	2
Staphylococci	3	1	—
Diphtheroids	2	1	—
taphylococci and bacilli	1	1	1
Unidentified diplococcus	1	—	—
nclusion bodies	—	1	2

No fine conclusions can be drawn from these results. So far as this series goes it would appear that none of the organisms met in ophthalmia neonatorum are completely resistant to penicillin. A rather surprising feature emerges with he three cases of inclusion blennorrhoea present: theoretically no result would be expected, but in two cases there was an initial recovery, only to be followed by a relapse.

The 22 cases treated with penicillin in a concentration of 1,500 units per c.cm. bear out the efficacy of the drug for the variety of causal organisms of ophthalmia. As can be seen rom Table I, treatment was successful in the 5 cases due to he gonococcus, the 9 caused by staphylococci, the 3 in which taphylococci and bacilli were present, and in the 2 in which nclusion bodies were found; 2 further cases in which no organisms or inclusion bodies were present also responded to penicillin treatment. No relapses were observed in this series, nd the only failure was a case in which no organisms were ound in the smear and the culture showed diphtheroids.

It would therefore appear that penicillin is effective over he whole range of causal organisms with the possible excep- ion of diphtheroids—though even here two cases responded to enicillin in a concentration of 1;000 and 1,500 units respec- ively, and a third case showed a partial response to peni- illin (1,500 units per c.cm.).

With the limited material so far investigated it is not possible o assess whether the different causal organisms respond to varying degree to penicillin treatment. The problem is, moreover, complicated by the fact that it is not always possible to ssess the significance of bacteriological findings in ophthalmia neonatorum. *Staph. albus*, diphtheroids, and some other bacilli re generally regarded as non-pathogenic. Yet it is worth noting that three of the seven cases treated with penicillin in concentration of 2,500 units and requiring treatment for more than 50 hours showed diphtheroids—one of them in associa- on with *Staph. albus*. In no case in which diphtheroids were found was there a rapid clinical cure. The bacteriological findings in the 7 cases requiring over 50 hours of treatment are of interest (Table III).

TABLE III

Smear	Culture	Inclusion Bodies	Duration of Treatment
Diphtheroids	Staph. aureus	Absent	100 hours
"	" "	"	" "
"	Staph. albus	"	50 "
Staphylococcus	Staph. aureus	"	60 "
Negative	Negative	"	70 "
"	"	Present	78 "
"	Staph. aureus	"	100 "

Cases showing diphtheroids or inclusion bodies would therefore appear to be most resistant to penicillin therapy. (*Staph. aureus*, though it appears three times in these 7 cases, is not in itself resistant to penicillin, as was evident from the excellent response in 6 other cases.)

Sulphonamide-resistant Cases

Five cases among the first 25 were treated with penicillin after a poor or protracted response to sulphonamides. Three of these were cases of gonococcal ophthalmia and responded well to penicillin, used in concentrations of 500, 1,000, and 1,500 units respectively. In the fourth case *Staph. aureus*, and in a fifth diphtheroids, were present; in both these cases there was a satisfactory response to penicillin in a concentration of 1,500 units per c.cm. Initially the first case had been treated by sulphathiazole for 12 days, and the four others by sulphamezathine for 5½, 12, 5½, and 23 days, respectively. Clinical cure by penicillin took place in 3, 4, 2, and 3 days respectively in the first four cases and in 18 hours in the fifth case.

Mode of Use

On admission the infant's eyes are irrigated with half-normal saline at room temperature and one drop of penicillin is instilled. Irrigation is also carried out before each further instillation of penicillin so long as there is any discharge. With penicillin in a concentration of 2,500 units per c.cm. irrigation is generally not necessary after 6 hours. Penicillin is continued for 48 hours after apparent clinical cure, at two-hourly intervals during the day and three-hourly at night. The drug is well tolerated by the infant's eye. Occasionally a mild transitory flushing of the conjunctiva is observed.

Comparison with General Sulphonamide Therapy

Until a standardized technique for local penicillin therapy is established no useful comparison with general sulphonamide therapy can be made. Local therapy has obvious advantages, and, moreover, avoids the danger of sensitization that the oral administration of sulphonamides carries. Frequent irrigations are, however, a trial to the infant and a considerable burden on the nurse. The present results promise to reduce these to a tolerable minimum. The dramatic results obtained by the sulphonamides are paralleled by those given by penicillin.

Summary

A total of 47 cases of ophthalmia neonatorum treated by the local application of penicillin in the form of drops is reported. Concentrations of 500, 1,000, 1,500, and 2,500 Oxford units per c.cm. were used.

An increasing proportion of satisfactory results was obtained with increase in the concentration of the drops used, the proportions in the four series being 3 out of 8, 4 out of 7, 6 out of 10, and 21 out of 22 respectively.

In adequate concentration penicillin appears to be effective against all the common causal organisms of ophthalmia neonatorum, including the virus of inclusion blennorrhoea.

It is likely that some forms of ophthalmia neonatorum respond more readily to penicillin than others. On the whole the results are of the same order as those obtained with the sulphonamides.

We are indebted to Dr. E. N. Young of the Southern Group (L.C.C.) Laboratories for her painstaking bacteriological examinations, and to the Matron and Sister Condon of White Oak Hospital for their collaboration. We are grateful to Prof. Sir Alexander Fleming for his interest and help.

PREPARATION OF PURIFIED PENICILLIN

BY

F. M. BERGER, M.D.

Assistant Bacteriologist, Public Health Laboratory, County Hall, Wakefield

This communication describes a simple and inexpensive method of preparing purified penicillin suitable for systemic use. The method can be carried out with the equipment available in most bacteriological laboratories. Production of penicillin in bacteriological laboratories would augment the supplies and make penicillin available to patients who otherwise could not be treated by this valuable drug.

Cultivation of the Mould

The mould *Penicillium notatum* was obtained from Sir Alexander Fleming. It was grown on a modified Czapek-Dox medium, using lactose instead of glucose (Taylor, 1943), corn-steep liquor instead of yeast extract (Clifton, 1943), and adding traces of zinc (Foster *et al.*, 1943). Yields of penicillin of 30 to 40 units per ml. were regularly obtained on this medium. The mould was grown at room temperature. The antibacterial activity was assayed by the cylinder-plate method (Heatley, 1944) and the tube-dilution method (Fleming, 1942).

Penicillin for Systemic Administration

Methods for extraction and purification of penicillin are all based on the observation that this substance can be extracted from strongly acidified aqueous solutions into ether, amyl acetate, or chloroform, and re-extracted from the organic solvent into water at *p*H 7 (Clutterbuck *et al.*, 1932 ; Abraham *et al.*, 1941 ; Meyer *et al.*, 1942). Further purification is achieved by chromatographic methods (Abraham and Chain, 1942 ; Catch *et al.*, 1942).

These methods proved very laborious and uneconomical, and therefore quite unsuitable for routine laboratory use. Meyer *et al.* (1942) claimed for their method a yield of over 50% of the original potency. Abraham *et al.* (1941) obtained in a form suitable for intravenous injection only about a third of the penicillin which had been present in the crude culture filtrate. The considerable losses of penicillin during purification by these methods were chiefly due to the rapid destruction of penicillin in strongly acid solutions, particularly when extraction was done at room temperature. To minimize losses, extraction had to be carried out in the ice-chest. Other features of these methods which have been found inconvenient were the large bulk of the solvents required and the long period of time (4 to 12 hours) which had to be allowed for complete separation of the amyl acetate–culture fluid mixture. Chromatographic methods for further purification of penicillin were too laborious and wasteful for routine purposes.

A search was made for a solvent which would extract penicillin from aqueous solutions at a *p*H not harmful to penicillin. It was found that most of the antibacterial substance could be extracted by n-butyl alcohol from culture filtrates adjusted to *p*H 6.4 (Berger, 1944), at which penicillin is most stable. Before extraction with butyl alcohol most of the inactive pigments and other impurities could be removed from the culture fluid by precipitation with ammonium sulphate. The salting out of impurities with ammonium sulphate did not result in any loss of antibacterial potency of the filtrate, and incidentally caused still more complete extraction of penicillin by butyl alcohol. Further experiments have shown that the solubility of penicillin in butyl alcohol is considerably greater than in the culture fluid at *p*H 6.4, thus allowing extraction with relatively small amounts of solvent. Penicillin dissolved in butyl alcohol was quite stable. Two samples of sodium penicillin obtained from the same butyl alcohol extract—one immediately after extraction and the other after having been kept in butyl alcohol for 48 hours in the ice-chest—contained the same amount of penicillin. The butyl alcohol–culture fluid mixture separated well, separation being complete after 10 to 15 minutes.

Penicillin was precipitated from butyl alcohol by light petroleum ether and obtained as an aqueous solution of the sodium salt by addition of a suitable quantity of sodium bicarbonate solution. During this procedure further purification of penicillin was achieved as certain impurities were left behind in the organic solvents. At this stage a fifteenfold to fortyfold concentration of penicillin could be obtained, and although extraction was carried out at room temperature the losses of penicillin were never greater than 15%, and were as a rule as small as 5%, of the amount present in the culture fluid.

Penicillin solutions were further purified by extraction into chloroform at *p*H 3.6 in the presence of ammonium sulphate (Meyer *et al.*, 1942). The addition of sodium bicarbonate solution to the chloroform extract again yielded an aqueous solution of sodium penicillin. The losses during this stage of purification were small, and usually less than 5% when the penicillin solution was well chilled before acidification. A further tenfold concentration was achieved by the chloroform extraction, and solutions of sodium penicillin containing 3,000 to 4,500 units per ml. were finally obtained.

Technical Details

The technical details of the method were as follows: The culture fluid was adjusted with 20% phosphoric acid to *p*H 6.4 The Lovibond comparator, with bromothymol blue as indicator, was used for this purpose. The culture fluid was then cooled in the ice-chest and 40% of ammonium sulphate was dissolved in it. The precipitate which formed was filtered off in the ice-chest through a Chardin filter paper. Five volumes of the filtrate were then extracted by shaking in a separating-funnel with one volume of butyl alcohol, and after separation the extracted culture fluid was discarded. To the butyl alcohol extract were then added an equal volume of light petroleum ether and one-eighth of the total volume of the mixture of 2% sodium bicarbonate solution. The butyl alcohol–petroleum ether mixture was extracted for a second time with a fresh portion of the 2% sodium bicarbonate solution.

The first extract of sodium penicillin, after having been chilled to approximately 4° C., was adjusted to *p*H 3.6 with 20% phosphoric acid, using the capillator method with bromophenol blue as indicator. Again 40% of ammonium sulphate was dissolved in the acidified penicillin solution, which was then extracted with an equal volume of chloroform. After separation penicillin was extracted into sodium bicarbonate solution by shaking ten volumes of the chloroform extract with one volume of 2% sodium bicarbonate solution. The chloroform was then extracted for a second and third time with fresh portions of sodium bicarbonate solution. The accompanying table gives the results obtained in a typical experiment.

Table showing Results obtained with the Butyl Alcohol Extraction Method followed by Further Purification and Concentration of the First Extract by the Chloroform Method

No.	Sample	Units per ml.	Volume of Fluid in ml.	Total Units	Percentage of Units Recovered
1	Culture fluid	31·6	14,000	442,400	—
2	1st extract from butyl alcohol	384·5	980	376,810	85·1
3	2nd extract from butyl alcohol	55·0	850	46,750	10·5
4	Extracted culture fluid ..	0·5	14,000	7,000	—
5	1st extract from chloroform made from No. 2	3,156·6	100	315,660	83·7
6	2nd extract from chloroform made from No. 2	489·7	100	48,970	12·9
7	3rd extract from chloroform made from No. 2	40·7	100	4,070	1·0
8	No. 2, after chloroform extraction	3·5	980	3,430	—

The aqueous solutions of penicillin were then adjusted to approximately *p*H 6.6 with dilute phosphoric acid. When kept in the ice-chest they retained their full potency for at least two months. The penicillin solutions were sterilized by passing through a Seitz filter; they were then stored in sealed ampoules and used for systemic treatment of patients. These chloroform-free penicillin solutions retained their full antibacterial potency at 4° C. for at least a further six weeks. The penicillin solutions could be freeze-dried without difficulty.

Second extracts from the butyl alcohol and the second and third extracts from chloroform were further purified and concentrated by the chloroform method to give a product assaying 250 to 500 units per ml. These solutions were incorporated into creams or used as drops for treatment of infections of the eye.

Before dispensing, the penicillin solutions were tested for sterility. Suitable amounts of penicillase, prepared according to Harper's (1943) method, were added to 1-ml. quantities of the penicillin solution and incubated aerobically and anaerobically in heart broth for three days. The penicillin solutions appeared to be non-toxic.

Rabbits injected intravenously with 20 ml. of a solution containing 0,000 units of sodium penicillin did not show any immediate or delayed reactions. Intracutaneous injections into the abdominal wall of rabbits and guinea-pigs did not cause any local inflammatory reactions, and the cutaneous swelling arising from the injection rapidly disappeared.

Morgan *et al.* (1944) when administering penicillin intravenously by the continuous-drip method noticed the development of thrombosis or thrombophlebitis in a large proportion of their cases. In view of these experiences intravenous application was not tried; the intramuscular route was employed exclusively. Usually 4 to 6 ml. of the penicillin solution (about 12,000 to 18,000 units) was injected every three hours. The continuous-intramuscular-drip method was also used in suitable cases, giving 80,000 to 100,000 units in 24 hours. Up to the present more than 40 patients suffering from various diseases due to penicillin-sensitive organisms were successfully treated in this way. Details of the clinical results will be published later. The injections of penicillin did not cause any immediate or delayed painful sensations, and no irritative or inflammatory reactions were observed.

Penicillin was also repeatedly injected intrathecally in two cases of pneumococcal meningitis and one case of streptococcal meningitis. The injections were therapeutically effective, were well tolerated, and did not cause any untoward symptoms.

Penicillin for Local Treatment

Crude culture filtrates containing as little as 2 to 10 units of penicillin per ml. have been used successfully by Pulvertaft (1943), Alston (1944), and Hobson (1944) for treatment of many localized infections. The clinical use of crude culture filtrates appears inadvisable and potentially dangerous for two reasons. First, such filtrates always contain large amounts of protein, which is also produced by the mould and secreted into the culture fluid. The repeated application of such fluids to large raw surfaces is likely to lead to sensitization—a point also made by Raper and Coghill (1943) in connexion with "home-made" penicillin. Secondly, culture filtrates from media which do not contain yeast extract or corn-steep liquor may contain notatin (Kocholaty, 1942; Coulthard *et al.*, 1942; Roberts *et al.*, 1943), a potent antibacterial substance of extreme toxicity.

Clutterbuck *et al.* (1932) found that by adjusting the fluid to *p*H 3.6 most of the protein and a considerable proportion of pigment could be flocculated and filtered off from the culture fluid without loss of penicillin. This method has been successfully employed for this purpose, and incidentally the gummy substances formed from the corn-steep liquor during autoclaving were precipitated out at the same time. Kocholaty (1943) found that notatin is not formed in cultures of *P. notatum* which contain corn-steep liquor.

The protein-free penicillin solutions were not toxic. Two rabbits, weighing about 1,600 g. each, were injected with 50 ml. intravenously in 10-ml. portions in the course of two days. The animals did not show any immediate or delayed reactions of any kind. The protein-free penicillin solutions have been used successfully in the treatment of extensive infected burns, wounds, abscesses, ulcers, discharging sinuses, throat and ear infections, empyemata, and gonococcal vulvovaginitis, and in selected cases of osteomyelitis and compound fractures. The penicillin solutions proved non-irritating and did not cause untoward symptoms in any case. Manifestations of allergy were not observed even when application of penicillin was continued for a month or longer.

Summary

A simple and efficient method of preparing purified penicillin for systemic treatment is described.

Intramuscular injections of penicillin solutions obtained with this method were therapeutically effective, were painless, and did not cause untoward effects of any kind.

This work has been done under the direction of Prof. P. L. Sutherland, to whom I am indebted for many valuable suggestions and for help and advice throughout the course of the investigation. Thanks are due to Sir Alexander Fleming for a subculture of the mould; to Dr. J. W. Trevan, of the Wellcome Research Laboratories, for a sample of standardized penicillin; and to Dr. D. Engel, medical superintendent of Staincliffe County Hospital, Dewsbury, for clinical application of the penicillin. Acknowledgments are also due to Mrs. B. Berger, Mr. G. Denton, and Mr. H. Schofield for technical assistance.

THYROID HYPERPLASIA AFTER PROLONGED EXCESSIVE DOSAGE WITH THIOURACIL

BY

J. B. DONALD, L.R.C.P.Ed.
Clinical Tutor, Royal Infirmary, Edinburgh

AND

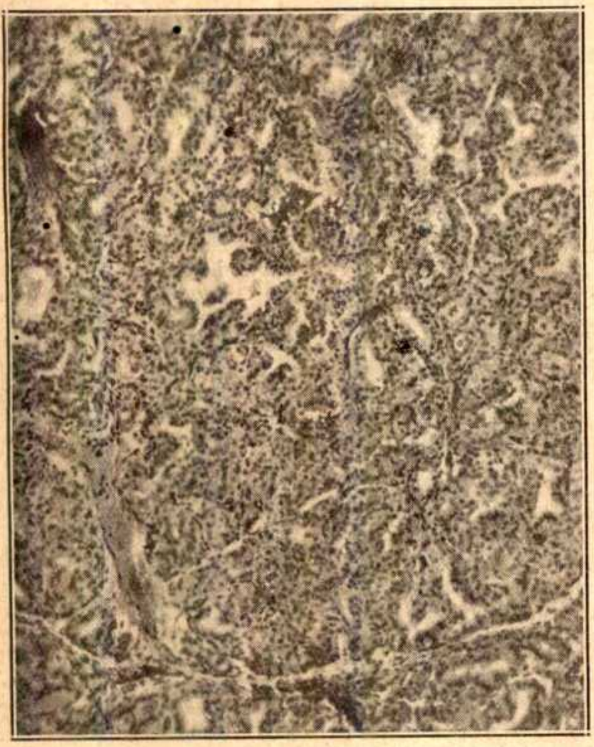
D. M. DUNLOP, M.D., F.R.C.P.Ed.
Professor of Therapeutics and Clinical Medicine, Edinburgh University

During the past year we have treated with thiouracil a total of 31 patients suffering from thyrotoxicosis. The results obtained are very similar to those noted by other workers. They are on the whole most encouraging, and comparable to those produced by successful thyroidectomy. Only one of the patients developed serious toxic reactions to the drug, consisting of leucopenia and signs of acute sensitivity. Another appeared relatively drug-resistant, and, in spite of prolonged treatment, thyrotoxic symptoms and signs persisted. With the exception of the case noted below no significant changes in the size of the goitres occurred as the result of treatment, though they usually became softer, and a transient slight increase in size was often noted at the menstrual period. It seems to be the general experience of other workers that thiouracil in therapeutic doses does not as a rule affect the size of the goitre significantly, but Himsworth (1944) has reported three cases in which the goitre increased considerably in size as the result of treatment with thiouracil—an effect which he attributes to overdosage.

There seems to be general agreement that the optimum dosage during the initial period of treatment should be 0.6 g. daily. This dosage should be kept up for from three to four weeks, at which time a fall in the basal metabolic rate has usually become significant. No increased effect is obtained by doubling the dose, as any additional quantity appears to be immediately excreted in the urine. There is as yet no definite consensus of opinion as to the dose required for maintenance treatment. There can be little doubt that 0.2 g. daily is adequate. We have never noticed any evidence of "escape" from the control of the drug when a reduction in the dosage has been made from 0.6 to 0.2 g. daily. There is no definite evidence, however, that 0.2 g. is the minimum dose required. We have latterly treated a number of patients with a maintenance dose of 0.1 g. daily, and it is our impression that this dose is quite sufficient. One case, through a misunderstanding, received an excessively large maintenance dose for a period of five and a half months.

Case Record

A female patient, aged 33, suffering from classical thyrotoxicosis, had experienced her first symptoms one year before admission to hospital. A small primary goitre was present. She was treated with 0.6 g. of thiouracil daily for 20 days, and was then given a maintenance dose of 0.2 g. daily for a week. She was discharged from hospital feeling very well. Her weight had increased by half a stone in a month, and her B.M.R. had fallen from + 55 to + 8. A mild tachycardia was the only residual sign of her thyrotoxicosis. She was told to continue to take 0.2 g. of thiouracil daily, but owing to a misunderstanding she actually took 0.4 g. As her home was in the far North of Scotland it was impossible for her to report to us regularly, and she was seen once a month by her own doctor. The first three reports from him were most satisfactory, but the fourth stated that she was not quite so well, though no specific symptom was noted beyond some lack of energy. By the fifth month this symptom had become pronounced, and a swelling of the neck was reported. The patient was immediately sent for, and on readmission, five and a half months after her discharge, was found to have a very large soft goitre. This was associated with a mild degree of myxoedema. Her weight had increased by one stone since discharge from hospital, her B.M.R. had fallen to −20, and her blood cholesterol had risen from 220 to 266 mg. per 100 c.cm. Her white blood count of 5,600 showed no significant alteration. Thiouracil was immediately stopped, and in two weeks' time she felt considerably better, her B.M.R. having risen from −20 to −3. No change had occurred, however, in the size or consistency of the goitre, and thyroidectomy was undertaken, principally for cosmetic reasons. At operation the thyroid was obviously enlarged, and was firm though not hard. The cut surface was typical of the hypertrophy associated with a primary toxic goitre which had not been treated by iodine. A section of the gland is shown in the accompanying photomicrograph. It can be seen that there is extreme parenchymatous hyperplasia and an almost complete absence of colloid, the picture being similar to that produced by Mackenzie in animals treated with goitrogenic substances. After the operation the patient made an uninterrupted recovery, and was discharged home feeling well.



Comment

It is thought worth while to record this case as providing another instance to those noted by Himsworth of thiouracil causing a great enlargement of the goitre in a previously thyrotoxic patient. It gives practical proof of the theoretical assumption that if the pituitary is stimulated to produce excess thyrotrophic hormone by overdosage with thiouracil an increase in the size of the goitre will occur similar to the hyperplasia of the thyroid produced in experimental animals by thiourea and its derivatives, and by sulphaguanidine. A rapid and significant enlargement of the goitre in a patient under treatment with thiouracil may thus be evidence of overdosage.

Medical Memoranda

A Method of Administering Systemic Penicillin

Owing to the shortage of rubber tubing systemic penicillin is being administered by 3-hourly intramuscular injections, and it has been found that a good many patients complain of the pain and discomfort, and "come to dread the needle." The following method has been adopted and found satisfactory.

Pressure-tubing, outside diameter 1/4 in., length 3/4 in., is worked over the intramuscular needle and a glass cap applied to seal off (Fig. 1). The intramuscular needle is fixed in a suitable site with elastoplast strapping. Another strip of elastoplast is applied over the first, the projecting rubber tubing with glass cap is wrapped in sterile gauze, and the elastoplast is fixed in place. 15,000 units of penicillin in 1.5 c.cm. are drawn up into an all-glass syringe, and the needle removed. The nozzle of the syringe is inserted into the rubber tubing, which is steadied by forceps, injection given, and a sterile glass cap applied. Sterile gauze is wrapped round and elastoplast is reapplied (Fig. 2). The intramuscular needle can remain in place for four days without changing to a new site.

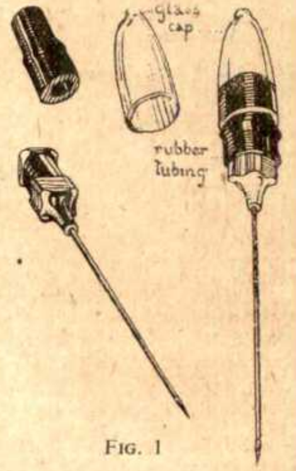

FIG. 1

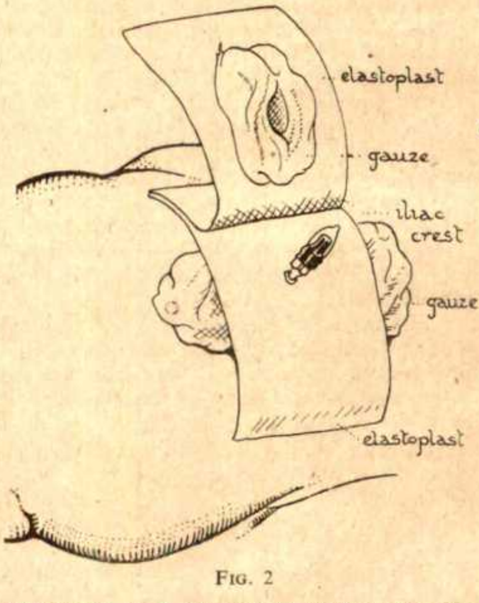

FIG. 2

I wish to thank Mrs. W. K. Somerton for the illustrations, Mr. Garner of the pathological department for the suggestion of the glass cap, and Dr Shepherd, the medical superintendent, for permission to publish.

Barnsley Hall Emergency Hospital.

A Case of Meningococcal Meningitis Treated with Penicillin

Since little is at present known about the effect of penicillin in meningococcal infections this case is considered worth recording.

CASE RECORD

A male child aged 18 months was admitted with a four-days history of repeated vomiting after all feeds. Previously he had been quite well. On the day before admission his mother had noticed that he felt hot and had a rash on his chest. There was no urinary retention and the bowels were normal. He had had gastro-enteritis at 2 months and at 6 months of age. The gain in weight had been good. On examination the child looked ill, being pale and lethargic. The anterior fontanelle was closed. There was slight diminution of skin elasticity. Some fading petechiae could just be seen on the thorax. The posterior cervical muscles were rigid, opisthotonos was present, and a positive Kernig's sign and Brudzinski's neck sign were found. The C.N.S. showed normal cranial nerves and reflexes apart rom absent abdominals. No abnormality was detected clinically in he chest, cardiovascular system, abdomen, throat, or eardrums, and the urine was normal.

Lumbar puncture on admission revealed a turbid C.S.F. under pressure: cells, 600 per c.mm., of which 66% were polymorphs; rotein, 100 mg. per 100 c.cm.—globulin test positive; sugar, present but reduced; chlorides, 680 mg. per 100 c.cm. Microscopy showed numerous extra- and intra-cellular diplococci. Culture yielded a pure growth of *N. meningitidis* which proved sensitive to penicillin nd sulphonamides. A blood count done at the same time showed R.B.C. 4,650,000 per c.mm., Hb 12.5 g.%, W.B.C. 16,200 per c.mm., of which polymorphonuclear cells comprised 59%, lymphocytes 29%, nd monocytes 12%.

Shortly after being admitted the child had a convulsion and was omatose. As an alternative to intramuscular sulphonamide a request was made for penicillin. This was supplied and an intramuscular drip set up containing 67,500 units in 16 fl. oz. of 0.9% aline. The temperature was then 101.5°, pulse 122. Overnight the temperature rose to 103°. Owing to poor absorption only 23,000 units were given in the first 24 hours after the drip was started. During the second period of 24 hours 112,000 units were given, made up in 0.45% saline, about 8 fl. oz. being used. The patient was now taking fluids by mouth. At this time the urine contained acetone and reduced Benedict's reagent fully.

Seventy-two hours after the start of penicillin administration 202,500 units absorbed) the rectal temperature was 99.5° and the child had so much improved that he recognized his parents and took hold of toys offered to him. Neck rigidity, though still present, was less marked. A second lumbar puncture showed a clear specimen, with cells 120 per c.mm. and chlorides 735 mg. per 100 c.cm. Culture yielded no organism, and the C.S.F. inhibited growth of the standard Oxford strain of staphylococcus.

Sulphamezathine was now given orally (0.5 g., 6-hourly), but ten hours later the temperature rose to 104°. A further course of penicillin was then started, 202,500 units being given during the next three days. By this time the temperature had fallen to 99° (rectal) and the child was able to walk about his cot, appearing normal in every way. He has since made an uneventful recovery. Total penicillin, 405,000 units in 6 days.

COMMENT

While under normal circumstances penicillin given intramuscularly does not enter the C.S.F., the observations in this case suggest that in the abnormal conditions of meningitis it may do so. It is evident that the dose given in the first 24 hours was inadequate. Penicillin should have been continued after 72 hours without a pause.

The continuous intramuscular drip was employed for the following reasons: (1) steady maintenance of blood level; (2) little disturbance of patient—0.1% novocain was included in the drip; (3) more numerous sites available. The daily dose was made up every 24 hours. A fresh drip apparatus was used each day, the whole being assembled complete with needle and then sterilized immediately before use. The outer sides of the left and right thighs were used alternately, the skin being cleansed with 2% C.T.A.B. and flavine in spirit.

*I am indebted to Dr. Stanley Wyard, senior physician, and to Dr. Richard Hollick, R.M.O., for permission to publish this case.

House-physician, Victoria Hospital for Children, Chelsea.

A Case of Weil's Disease Treated with Penicillin

The following record of a case of Weil's disease has two points of interest. The first is the clearing of the leptospira from the urine after only 6 injections of penicillin, coincident with rapid clinical improvement; the second, the demonstration of leptospira in the blood and urine on the day that the agglutination titre was as high as 1 in 1600.

CASE HISTORY

A private soldier aged 38 was invalided from France with pyrexia of six days' duration and reached this hospital on the evening of Sept. 12, 1944.

The patient reported sick on Sept. 7, complaining of a severe frontal headache and a sensation of chilliness and shivering. His temperature was 102.8° F. Next day he complained of generalized aching and soreness of the eyes. His conjunctivae were injected and his temperature was now 103° F. His liver was palpable and tender, and he vomited continuously. His blood was negative for malaria parasites and *Leptospira icterohaemorrhagiae*. There was a mild leucocytosis of 12,800. He was evacuated by air on Sept. 11, and the last entry on his medical card stated that his general condition was poor.

Clinical examination on arrival at the hospital showed that he was now lightly jaundiced and his conjunctivae were heavily injected. He stated that during August he had bathed frequently in a rat-infested river. On the 13th, examination of his urine revealed the presence of large numbers of spirochaetes morphologically identical with *L. icterohaemorrhagiae*. Blood was taken for the agglutination test and a few drops were examined by dark-ground illumination. Surprisingly, leptospira similar to those in the urine were easily found. Later the report from Prof. Gardiner, of Oxford, stated that the serum was positive for agglutination of *L. icterohaemorrhagiae* to a titre of 1 in 1600.

Penicillin therapy was started at 6 p.m. The dosage was 20,000 units intramuscularly three-hourly until Sept. 17 and then four-hourly until it was stopped on the 20th. The total dosage was 900,000 units. Before the penicillin was begun the patient complained of a marked degree of general malaise. The following morning he said he felt all right and thought himself fit enough to get up. However, his temperature did not become normal until the 16th. Leptospira could not be demonstrated in his urine or blood from 9 a.m. on the 14th onwards. Specimens of his urine were examined daily until the 30th, and in none of them was the organism discovered. The patient did not develop any after-fever, and was discharged perfectly well on Sept. 30.

Internal Hydrocephalus complicating Pneumococcal Meningitis Treated with Penicillin after Sulphonamides

Internal hydrocephalus is a well-known complication of post-basic meningococcal meningitis, but the following case shows that when the clinical course of the disease has been considerably prolonged by therapeutic measures it can arise also in infections due to the pneumococcus.

CASE REPORT

A male infant aged 2 months was admitted to hospital, having been unwell for a few hours, during which he had one convulsion. On examination he was found to be extremely ill, vomiting brown material, and grossly dehydrated. His temperature was 100.6° F., pulse uncountable, and respiration rate 40 a minute. No clinical signs were found in his chest or the central nervous system, but the C.S.F. was turbid and contained Gram-positive diplococci. On culture a pneumococcus was isolated which proved lethal to mice.

Subcutaneous saline was administered and 0.5 g. of sulphapyridine by mouth every four hours, but after 5.5 g had been given this was stopped on account of persistent vomiting. This treatment was accompanied by a fall in the temperature to 97° F., but next day, the fourth after admission, it rose to 101.4°. Sulphathiazole was then administered in the same dosage, but starting with 1 g. The temperature did not settle and the infant remained very ill. On the seventh day 10,000 units of penicillin were injected into the right lateral ventricle, after which 2,000 units were given intramuscularly every four hours. By the ninth day the C.S.F. contained only a few cocci; these were avirulent to mice. On the next day the temperature became steady at a normal level. The child's general improvement was pronounced, and no more organisms were recovered from the C.S.F. On the seventeenth day he became unwell again, and developed attacks of twitching with cyanosis and some vomiting. No C.S.F. could be obtained from the spinal canal in the lumbar region, but that in the basal cisterns was under raised pressure. It contained 600 mg. of protein per 100 c.cm. and 60 lymphocytes per c.mm.; no organisms were seen in it, and cultures were sterile. The child died two days later, on the twentieth day after admission, the illness having lasted for 21 days altogether.

Findings at Necropsy.—Nothing abnormal was found outside the central nervous system. The brain was fixed by withdrawing fluid from the cisterns and ventricles and replacing it with formalin 24 hours before opening the skull. Films of this fluid showed effete polymorphs, some of which contained degenerate-looking Gram-positive cocci. Cultures of the C.S.F. were again sterile. Many adhesions were present between the pachy- and lepto-meninges, and a dense fibrinous exudate surrounded the brain stem and filled the cisterns. All the cerebral ventricles were markedly dilated down to and including the fourth. They all contained turbid fluid and fibrin coagula. In histological sections of the meninges the exudate was seen to contain many polymorphs. The choroid plexus was covered with a similar exudate, but this contained many Gram-positive cocci as well.

DISCUSSION

Death was caused by internal hydrocephalus due to the fibrinous exudate. In their series of 16 cases of pneumococcal meningitis treated with penicillin Cairns, Duthie, Lewin, and Smith (1944) had one case of obstruction of the aqueduct of Sylvius, but this was apparently due to pressure of an abscess. Evans (1944) saw no such condition in his small series of cases of purulent meningitis. The likelihood of the development of such a fibrinous exudate in the early stages of the infection would seem to be another reason for treating all cases of pneumococcal meningitis with penicillin as early as possible—a procedure already recommended by Cairns *et al.* in their paper.

I have to thank my colleague Dr. P. Forgacs, under whose care the child was, for his co-operation.

Treatment of Ulcers by Plaster Casts

The Meru district of Kenya is inhabited by about 120,000 Africans and is heavily infected with yaws. The standard of living is very poor, and food shortages periodically lead to outbreaks of ulcers, some of which approximate to a nutritional type; others are simply yaws, and no doubt many are of mixed type. In the comments that follow no endeavour is made to distinguish the types, as all are equally intractable in certain cases and all react equally well to plaster-of-Paris treatment.

Late in 1943 several bad ulcer cases were admitted about the same time. One was so severe that amputation seemed the likely solution. All meant dressings, which were a misery to the nurses, the patients, and the wash-boys who had to deal with piles of filthy dressings. They were also a heavy expense, as doubtless many of the worst dressings were thrown away surreptitiously by the wash-boys. All these patients were getting N.A.B. and bismuth, a diet sufficient to increase the weight in the other patients, tonics, and treatment for worms if required. Locally, we rang the changes on eusol, hot foments, dry dressings, hydrarg. perchlor., cod-liver-oil ointment, elastoplast, copper sulphate, and carbolic (which usually required morphine preparation). There was no specific, and some patients treated earlier in the year had long spells in hospital.

Then we tried plaster-of-Paris casts (P.P.) and the whole situation changed. Six of the worst cases were scraped, or encased without scraping, and their reactions were watched carefully. The pain eased within two days, and the temperature dropped within about five days; but the most noticeable thing was the mental change—from despair to cheerfulness and joking. This treatment has not failed, in any of some 40 cases, to lead to the casting off of sloughs, formation of healthy granulations, and proliferation of skin. The following are brief notes of 5 typical cases.

CASE HISTORIES

Case 1.—Chuka female aged 35, admitted Nov. 4, 1943. Large ulcer 7 in. in length, extending almost right round the leg, leaving a strip of healthy skin 2 in. wide over peronei. Greenish base, with sloughing muscles. Offensive smell and very painful. Warned probably need amputation unless case reacted unexpectedly well. On Nov. 10, under ethyl chloride general anaesthesia, the sore was scraped, powdered with sulphanilamide, covered with lint on which zipp had been smeared, and encased in P.P. Two days later she had no pain; her temperature was lower, though the pulse continued at 120. Her general condition showed rapid improvement; her face filled out, and on Nov. 19, impelled by curiosity, we removed the cast. Almost the whole area was covered with healthy granulations. There was no smell, and no sloughs were present except one small tag, which was cut off. New P.P. was applied: 17 days later, when this was removed, the whole area was healthy and new skin had proliferated for half an inch all round. She could walk with a slight limp. Next day she was skin-grafted with Thiersch grafts, and mosquito netting was superimposed. Hot foments were applied. After a little delay owing to blebs forming under the new skin, she walked off home, healed, 6 weeks from application of the first P.P.

Case 2.—Meru male aged 1. Big toe amputated by ulcerative process. Head of metatarsal exposed. Smelly, with oedematous undermined edges. One month's duration. Dressings applied for 14 days. Some improvement, but still very unhealthy. P.P. applied, and patient discharged. Returned in 14 days. The mother said the child was happy and had had no pain. On removal the sore was reduced from 1½ in. diameter to half that size. Healthy granulation over metatarsal. Sent out with dressings.

Case 3.—Meru male aged 20. Shallow ulcers round toes. Feet very sweaty. Treated with salicylic spirit, as considered possibly fungous. No improvement after 15 days. P.P. applied. Patient sent out. On return in a fortnight was soundly healed. No return in 3 months.

Case 4.—Meru male aged 23. Admitted Nov. 19, 1943. Ulcer 8-shaped, the centre being over the head of the second metatarsal; 5 in. in length—half on dorsum and half on sole; second toe gone. Foul and very painful. Edges raised and indurated. Swelling had caused big and third toes to be separated by 2 in., which area was occupied by the ulcer. On Nov. 20, without scraping, zipp and P.P. applied up to above the ankle. Much oozing necessitated more P.P. being added. A good patient, he waited for a month. On removal of plaster only a small linear sore remained—1½ in. by 1/2 in. He left rejoicing.

Case 5.—Embu female aged 10. Ulcers of toes and nail-beds extending on to dorsa and soles; raised oedematous edges and purulent bases; 9 months. Pain severe; much weeping over dressings. On Nov. 2, 1943, nails avulsed and ulcers scraped: no improvement. On Nov. 10 zipp and P.P. At once the whole picture changed. The patient had no further pain, and when the P.P. was removed on Nov. 29 most of the ulcer was healed and there were healthy granulations over the rest. The nail-beds were healthy. (This is an important point, as nail-bed infections usually prove most intractable.)

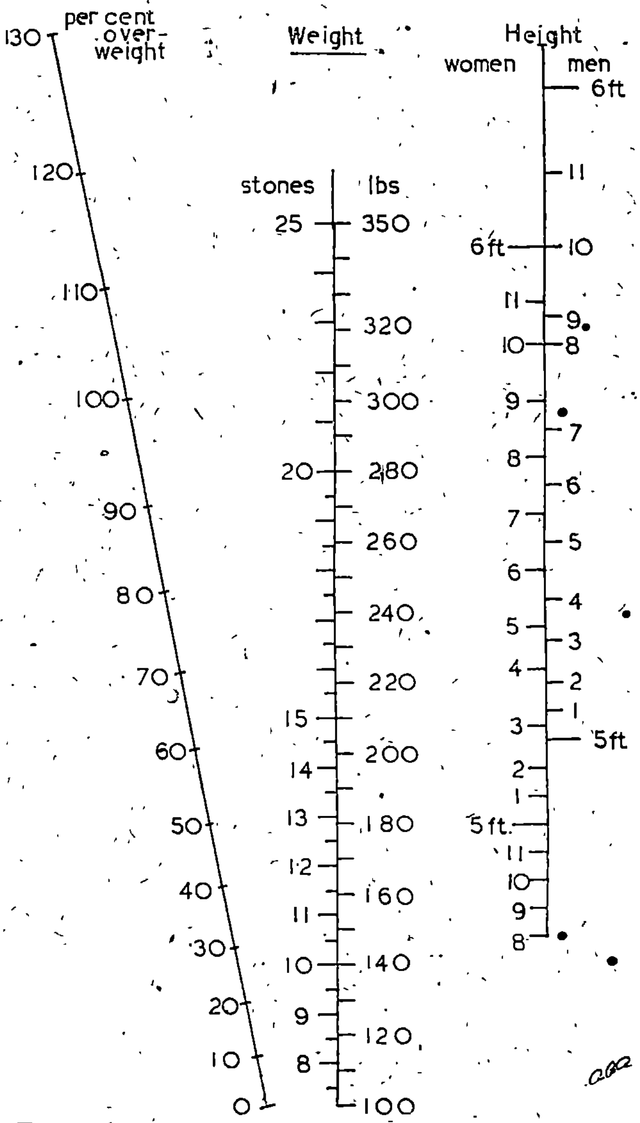
Other cases successfully treated include a leper with a linear crack across the sole, at the base of which the os calcis was exposed. Nothing had availed to heal till P.P. was tried. Case 10 in my series, which it would take up too much space to give in full, was similar to Case 1, except that she continued to have pain and a temperature—forcing us to take down the P.P. at weekly intervals. The result, however, was the same, and after 14 days' P.P. she was ready for grafting. At the moment of writing, on the 20th day, grafts have taken well and she is having treatment for foot-drop due to the position of the foot at rest while in her village. A high degree of anaemia did not prejudice the cleaning up or the taking of the grafts.

To summarize: by means of plaster-of-Paris casts, with or without scraping and application of sulphonamides and zipp, ulcers can be treated with comfort to patient and staff and much saving of expense. Some that would otherwise have to be admitted can be treated as out-patients. Granulation tissue forming under the casts takes grafts very well, and the growth of the skin edges is rapid and healthy.

Chogoria Hospital. CLIVE IRVINE, M.D.

A Nomogram for Percentage Increase of Body Weight over Ideal Weight

The nomogram illustrated has been designed to enable a rapid estimation of the degree of overweight in adults to be made. The scales have been prepared from the ideal weights given in a table by Newburgh (1942), which are adapted from those given by Fisk for average weights at age 30. The weights include clothes and the heights include shoes.



To use the nomogram, the height and weight are measured and a straight line joining the points on the height and weight scales is produced to cut the percentage scale. The point of intersection gives the percentage over ideal weight. If the zero point on the percentage scale is joined to the appropriate point on the height scale, the intersection on the weight scale gives the ideal weight.

Reviews

FACIAL RECONSTRUCTION

Traumatic Injuries of Facial Bones. By John B. Erich, M.S., D.D.S., M.D., Consultant in Laryngology, Oral and Plastic Surgery, Mayo Clinic, and Louie T. Austin, D.D.S., F.A.C.D., Head of Section on Dental Surgery, Mayo Clinic, in collaboration with Bureau of Medicine and Surgery, U.S. Navy. (Pp. 600; illustrated. 36s.) Philadelphia and London: W. B. Saunders Company.

Reconstructive Surgery of the Eyelids. By Wendell L. Hughes, M.D., F.A.C.S. (Pp. 160; illustrated. 21s.) London: Henry Kimpton.

aumatic Injuries of Facial Bones is businesslike and useful. he book is set out in the form of an atlas, with photographs patients, radiographs, or models on one side of the page, d full and detailed instructions for treatment on the other. us every possible variety of mandibular fracture is represented ostly in the form of plaster reconstructions), and the reader n quickly learn the appropriate treatment for each. The thors seem to prefer arch wires to cap splints for most of eir cases. Direct skeletal fixation is used when the fragments nnot be controlled without it. The different varieties of axillary fractures are next described. Here again arch wires e prominent, with fixation to a head-cap, either directly or directly. Malar and nasal fractures are treated on lines nilar to those employed in this country, except that internal lints are used inside the nose without anxiety. Multiple facial actures receive careful consideration, and their repair is gone to in great detail.

A considerable section of the book is devoted to bone-grafting the mandible, for which solid pieces of iliac bone are used, d a further section to restoration of facial contour, both by ay grafting and by cartilage transplants. The final section scribes the application of a plaster head-cap, the insertion of eletal pins, the details of wiring in all forms, and the construction of metal splints.

The book is well printed on good-quality paper (rare in home oductions), and the 333 illustrations could not be bettered. ere can hardly be a problem in injury of the facial bones r which an answer cannot be found quickly and easily in this anual. It is a first-class presentation of the subject.

The monograph *Reconstructive Surgery of the Eyelids* was epared as a thesis and is largely concerned with the repair eyelids after partial or complete removal for neoplasm, and such is a useful addition to a library.

The major part of the book is taken up with the historical velopment of plastic procedures, illustrated in the main from original papers. Unfortunately the illustrations have ffered by reduction and overcrowding, and it is not only ficult to make them out but also difficult to correlate the text, illustration, and the legend thereof. Nor is the text improved overburdening with names and reference numbers. Innumerle procedures are sketchily described, without any attempt at tical appraisal, which is of little value to the student. Thus, r example: "Judging by reports in the literature . . . in empting to reconstruct a fornix, if some living tissue is apped around the form it suffices whether it be a mucous mbrane or skin from the same individual, mucous membrane m another individual of the same species, fetal membrane, even conjunctiva from a foreign source, such as a rabbit." ould that it were so simple!

In the latter part of the book Dr. Hughes describes some of successful cases of replacement of complete lid losses, chiefly m the opposing lid and adjoining cheek tissues. This section well worthy of study, though to-day one would have preferred ditional information on wartime injuries. One cannot help miring the energy of the author in regimenting 451 erences.

MENTAL ABNORMALITY AND CRIME

ental Abnormality and Crime. Introductory Essays. By R. N. raig, W. N. East, R. D. Gillespie, E. Glover, D. K. Henderson, E. O. ewis, D. R. MacCalman, A. MacNiven, E. Miller, J. D. W. Pearce, R. Rees, G. de M. Rudolf, G. M. Scott. (Pp. 316. 18s.) London: acmillan and Co. 1944.

idies in crime must always be of interest to the medical ofession, since more and more is crime being recognized an individual disability, and more and more are social problems becoming linked with those of health. Of the papers so far published in the series *English Studies in Criminal Science* this is the most interesting to doctors in general, apart from those engaged in psychiatry. The thirteen essays which this book contains cover nearly all of the psychiatric aspects of criminology. One of particular interest is that by Dr. MacNiven, in which the question of responsibility is discussed, especially in relation to the M'Naghten rules. It is clear that partial responsibility will have to be more generally recognized, and indeterminate sentences for purposes of treatment be more often inflicted. Dr. Gillespie deals informatively with the connexions between the psychoneuroses and crime, and postulates that if crime is to rank as psychoneurotic there must be no real gain to the criminal, or the apparent gain must be shown not to be the real meaning of the act for the individual. The crime must be shown to be the outcome of conflict, and the criminal behaviour to be a substitute for or a compromise between the opposing tendencies. The criminal should be demonstrated to present other signs of psychoneuroses.

Dr. MacCalman's essay on traumatic neurosis in relation to compensation also merits study. As he points out, a single shock is seldom the sole cause of a breakdown, though it may precipitate this from a psychoneurotic background. Similarly neither work nor settlement in a lump sum is a panacea, for anxiety about capacity to work and financial security prolongs the illness. Early and complete psychological treatment is required, and without it results are likely to be poor. The section on juvenile delinquency is unimpressive, and gives a poor idea of all that is being done and all that has been found out in this branch of criminology. This is somewhat mitigated by an excellent report by Dr. Glover on the origins, methods of work, and results of the Institute for the Scientific Treatment of Delinquency. Altogether this interesting collection will well repay careful study.

TWO BOOKS ON NURSING

The Practice of Nursing. By Hilda M. Gration, S.R.N., S.C.M., D.N. (Pp. 420; illustrated. 12s. 6d.) London: Faber and Faber.

Clinical Procedures and their Background for Senior Nursing Students. By Agnes E. Pavey, S.R.N., D.N. (Pp. 331; illustrated. 8s. 6d.) London: Faber and Faber.

There are so many good textbooks on nursing that new additions not only must reach a high degree of perfection in detail but must preferably make some new method of approach. On the latter count Miss Hilda Gration's book on *The Practice of Nursing* certainly presents a more humane attitude than some books on this subject—when tested on such matters as the hour of waking, bed-making, and cups of tea! But there are errors in detail that impair its value. As early as page 15 a picture of a clinical thermometer upside down gives an uneasy feeling, aggravated by the spelling "albumen" on page 56 (for albumin in the urine), and "pulmonary tuberculosis" would have been better than "phthisis" on page 63. (The word "tuberculosis" does not even appear in the index.) The same old-fashioned terminology is perpetuated on page 156 with the use of "scruple," excluded from the *British Pharmacopoeia* many years ago. More serious faults are to be found. For example, the details of taking blood for a Wassermann test do not make it clear that the needle must be sterile, nor do they indicate the importance of rinsing with normal saline so as to avoid possible haemolysis. Another omission is that it is not made clear that all liquid milk is potentially dangerous; pasteurization is not mentioned, although as a concession milk is directed to be boiled for ill babies and for the newborn. It is a pity that a close study has revealed such faults, for the author has an attractive style and the illustrations are of good quality and well chosen.

Miss Agnes Pavey's book is open to similar fault-finding on grounds of accuracy and terminology. An appendix on "diseases, syndromes, and symptoms known by proper names" contains many "howlers." But a more serious criticism can be made: there is far too much here on details of diagnosis. Tests for liver efficiency and kidney function seem matters which should be outside even the senior nurse's curriculum, and surely the nurse does not need to know details of staining for the tubercle bacillus.

Notes on Books

A fourth edition has reached this country of *Public Health in South Africa*, by Prof. E. H. CLUVER, director of the South African Institute for Medical Research. Like its predecessors, this edition is addressed mainly to students of medicine, and the author has succeeded in his aim of presenting information in simple terms and in a concise form. It will also prove useful to the large body of workers all over the Union of South Africa who, in addition to medical officers, are concerned with the protection and promotion of public health. The descriptions of various public health services assume that the pre-war arrangements will continue; but, as the author says in his preface, no one can predict with any degree of accuracy what the medical organization will be after the war. The publishers are the Central News Agency, Ltd., Johannesburg.

The second of the two reports containing selected documents from the proceedings of the council of U.N.R.R.A. at its meeting at Montreal last September has now been published (H.M. Stationery Office; 1s.). Readers who are interested to know how supplies for immediate relief in liberated countries were estimated will find some account of it and of the creation of "stockpiles" of food in the statements of Lieut.-Gen. G. N. McCready and of the representative of the Combined Food Board. Difficulties and problems encountered in Italy, especially Naples, are described, and the publication also contains the text of the council's resolutions.

Preparations and Appliances

INSTRUMENT FOR CONTINUOUS AND ACCURATE ADMINISTRATION OF PENICILLIN INTRAMUSCULARLY

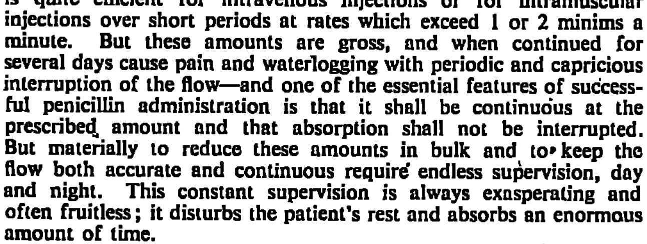
Dr. C. E. LAST, medical officer, Queen Mary's Hospital for Children (L.C.C.), Carshalton (evacuated to Dryburn Emergency Hospital, Durham), writes:

The difficulty of giving penicillin by continuous intramuscular drip is recognized by many; the difficulty being one of controlling and accurately regulating the amount of fluid given to such proportions as will be continuous and, at the same time, not cause too much pain and discomfort, nor waterlogging of the tissues.

The usual drip apparatus which is controlled by clamping a rubber tube, either with or without the assistance of capillary glass tubing, is quite efficient for intravenous injections or for intramuscular injections over short periods at rates which exceed 1 or 2 minims a minute. But these amounts are gross, and when continued for several days cause pain and waterlogging with periodic and capricious interruption of the flow—and one of the essential features of successful penicillin administration is that it shall be continuous at the prescribed amount and that absorption shall not be interrupted. But materially to reduce these amounts in bulk and to keep the flow both accurate and continuous require endless supervision, day and night. This constant supervision is always exasperating and often fruitless; it disturbs the patient's rest and absorbs an enormous amount of time.

Description of Apparatus

A very simple instrument has been designed and made to meet all these difficulties. A is a Record syringe which rests in a trough and is held by a suitable clip. B is a 3/8-in. screw with 16 threads to the inch passing through a metal housing supported on a pillar. CC are two parallel arms fixed at each of their ends in a brass disk or plate; the disk nearest the syringe is carried on a central bearing on the screw housing; the other disk has a central boss which is coupled to the spindle of the hour hand of a clock or small electric motor. D is a small clutch, controlled by a finger screw, which intervenes between the boss and the spindle. F is a detachable pin which transfixes the main screw and is held in position by a small finger screw. E is a clock or motor electrically driven. All the parts are aligned and mounted on a board.



The clock spindle or electric motor makes one complete revolution every hour and turns the parallel arms with it. The arms engage the pin which turns the screw, and, as the screw proceeds, the pin slides along the arms. The screw has 16 threads to the inch and therefore takes 16 hours to travel one inch; in 24 hours it travel 1½ in., pushing the piston of the syringe as it goes. The trav of 1½ in. of the piston of a 10-c.cm. syringe represents a trifle le than 8 c.cm. Therefore there is a continuous and positive delive at the nozzle of the syringe of fluid at the rate of, say, 8 c.cm. i 24 hours, or 1 c.cm. during every 3 hours. In minims this work out at 1 minim every 10 minutes 17 seconds, delivered punctual and without fail, no more and no less. A 20-c.cm. syringe woul deliver about 13½ c.cm. in 24 hours, or, say, 1 minim during eve 5 minutes 25 seconds.

Method of Use

100,000 to 120,000 units of penicillin are dissolved in 8 c.cm. 14 c.cm. as the case may be, and it is led through Southey's tubin and passes intramuscularly by means of a hypodermic needle, wit or without additional side holes—the instrument being placed on table 12 to 18 in. above the level of the patient. The connexio between the syringe and the tubing and the needle and the tubin are Record metal ends.

When a 24-hour run has been completed the finger screw co trolling the clutch is loosened and the screw B run back by hand the syringe is refilled, or, better still, a fresh syringe with a fres charge is taken, the exposed metal ends are flamed and reconnecte the moving parts repositioned, and another 24-hour run is starte Assembly, filling, and refilling only take a few moments; the syrin can be renewed without disturbing the needle and tubing, and needle can be changed without disturbing the syringe and tubin

Advantages and Precautions

Pain and inconvenience to the patient are practically absent, h sleep is not disturbed; and, as the small amount of penicill delivered is absorbed as fast as it arrives, there is no waterloggin The considerable amount of time spent by the nursing staff observations and adjustment is saved.

Children are easily dealt with. One little child aged 2 years wi osteomyelitis of the femur and sinuses was put in a double plast spica and a 16-days treatment of 100,000 units a day was carri out through a gap in the plaster over the only thigh available witho any distress or evidence of complaint. A 10-c.cm. syringe was us and the needle changed 6 times.

Under normal running conditions there is no "seeping" behi the piston, owing to the fact that there is a negative pressure in t syringe and tubing system. Seeping can only occur when an intern resistance is built up which more than neutralizes the negat pressure, that is equivalent to 12 to 18 in. of water. Needle blo is the main cause of this. Therefore seeping is to be regarded the warning that the needle requires changing. However, with t concentrations used, needle block has so far not occurred und 24 hours; 36 hours is a critical time, but there have been ma uninterrupted runs of 48 hours and a few of 3 days, when t needle is changed as a routine. Some authorities advocate a chan of needle every day and, with all discomfort reduced to a minimu this could not be a hardship to the patient. In addition to t evidence of "seep," a small glass pressure gauge is positioned the tubing system, which reveals very early any needle block; th gauge also has a "boost," which frequently enables an early bloc ing to be cleared.

The original experimental instrument was run off the back of standard alarum clock and has been in continuous use at the Drybu Emergency Hospital for the past 10 weeks. I also have in use the same hospital an instrument electrically driven and similar appearance to the one pictured here.

I am greatly indebted to Willen Bros. Ltd., of 44, New Cavendi Street, London, W.1, for the trouble they have taken in manufactu ing the instrument as illustrated, and for having made the vario changes and modifications that tests showed to be necessary. T final working drawings have been placed solely in their hands produce the instrument in accordance with the authorized design.

TYROTHRICIN

"Tyrothricin" is the new name given to the antibacterial substan extracted from cultures of *B. brevis*, as originally demonstrated Dubos. It is separable into two constituents—gramicidin (the na originally given to the whole extract), which is highly active again Gram-positive bacteria only, and tyrocidine, which is more to but acts also on some Gram-negative species. Tyrothricin is unsu able for the systemic treatment of bacterial infections, but is a ve powerful antiseptic when applied locally, and has been used succes fully for treating wounds, infections of the conjunctiva and corne and of the ear, nose, and throat; there are also favourable repo on its use in empyema and certain skin diseases. Tyrothricin h now been put on the market in England by Sharp and Dohme L (Mulford Biological Laboratories, Hoddesdon, Herts), who al publish a valuable booklet describing the history of its developme and indications for its use, with a useful bibliography.

Tyrothricin concentrate (human) Mulford is supplied in 1-c.c and 20-c.cm. vials of a solution containing 25 mg. per c.cm.; t is diluted fiftyfold or more in sterile distilled water for use.

THE NATURE OF PENICILLIN ACTION

has been generally accepted until recently that penicillin bacteriostatic rather than bactericidal. This has doubtss been a good thing, since it has encouraged attempts maintain continuous action for a long period; only in ese circumstances will any antiseptic substance, whatever e nature of its action, help to eliminate bacteria from fected tissues. But in recent months several workers in is country, notably J. W. Bigger,[1] have obtained evidence at penicillin, so far from merely restraining the growth bacteria, actually kills them. These observations have en prompted by a natural curiosity about the mechanism which penicillin achieves its effect. We are no longer ntent with the knowledge that a certain substance under ven conditions will kill a particular micro-organism: we nt to know by what chemical process this is brought out, and such knowledge has been obtained for a large riety of chemotherapeutic agents within the past few ars. Not only does it place treatment on a fully rational stead of a semi-empirical basis, but it may point the way the synthesis of related agents with extended powers.

There are several facts of which any explanation must ke account. One is the peculiar specificity of the action penicillin. Everyone knows that some bacteria are sceptible and others not, and that Gram-staining reaction es not without exception distinguish them; what is not generally recognized is that the degree of susceptibility so variable. Some species commonly classed as totally sistant are in fact affected by higher concentrations; ey include even the typhoid bacillus and salmonellas, d it was predicted several years ago by the Oxford rkers[2] that the treatment even of these infections may ove worth while when pure penicillin is freely available. her bacteria which most people dismiss from their minds ere penicillin is concerned appear in a new light in view the observations of H. F. Helmholz and C. Sung[3] on action of penicillin on bacteria in urine. No one has ught of treating with penicillin any urinary tract infecns except those due to staphylococci, but these authors ve shown that a concentration 90 times greater than the nimum necessary for *Staph. aureus* has the same effect *Str. faecalis,* while a 240-fold increase will bring in *oteus,* and a 900-fold some strains of *Bact. coli*; only *ct. aerogenes* and *Ps. pyocyanea* were unaffected at this d even a higher level. Owing to the very high concentions attained in the urine by systemic administration o at least of these relatively resistant organisms may cumb to treatment in this special situation only. These amples illustrate the enormous range of susceptibility different bacteria; the peculiarity in their constitution which accounts for this has yet to be discovered. Another fact of observation is the penicillin-induced change in morphology first observed by A. D. Gardner.[4] Cocci swell to thrice their normal size, and bacilli elongate themselves into monstrous threads; this change naturally gave birth to the idea that penicillin prevents bacterial division. A third noteworthy fact is the immense possible range of habituation to penicillin, at least in some species. Whatever the action of penicillin, it is one which the bacterial cell can learn to counter or circumvent; the studies of E. W. Todd and others, which are described on page 111 of this issue, show that *Staph. aureus* can be trained to withstand a concentration 3,000 times greater than the maximum tolerated by the original culture. Unlike the pneumococcus, which has been shown to retain this property in subsequent culture or mouse passage, this organism lost it rapidly in normal media. It is consoling to read that similar treatment applied to the gonococcus failed to induce any appreciable increase in resistance.[5]

A helpful method in determining the nature of chemotherapeutic effect is to identify substances which neutralize it; this was the path which led to success in the study of sulphonamide action. So far no application of this method to the study of penicillin has been discovered; one secret of its therapeutic success is the fact that penicillin acts equally well in any medium not actually destructive to it, including any body fluid, pus not excepted. Whether the substance recently extracted by W. M. M. Kirby[6] from penicillin-resistant staphylococci will be of any interest in this connexion remains to be seen; it is not penicillinase; and, indeed, the evidence seems clear that when normally susceptible bacteria acquire resistance to penicillin this change is not due to acquisition of the power to make this substance, nor do all naturally resistant species form it. Another possible line of approach is to study the influence on penicillin action of simple physical factors such as concentration and temperature, with a view at least to discovering whether their effects on penicillin and on ordinary disinfectants are the same. Such a study is described by L. P. Garrod in the opening paper of this issue, and appears to have brought to light one peculiar feature—namely, that increase in concentration above what by clinical standards is a very moderate level brings no added effect, and will indeed, if carried far enough with impure penicillin such as is now being used, actually diminish the rate of disinfection. Subject to the results of further studies, which will evidently be dependable only if conducted with pure material, it seems that within very wide limits the action of penicillin is indifferent to concentration; its full effect is exerted at a certain quite low level—probably well under 1 unit per ml.—and no addition to this will alter the result. This property, should it be verified, is peculiar and may well be significant. It has a distinct bearing on practical treatment and indicates a policy by which efficiency and economy can be combined.

Laboratory findings have also been translated into therapeutic policy of quite a different kind by Bigger,[7] whose argument rests on the observation that in a population of staphylococci, of which the vast majority are killed by penicillin overnight, a few survive even for days. Linking this with the hypothesis that penicillin kills only dividing cells, he attributes this survival to the existence of a few cells in a dormant condition; these "persisters" are assumed to be the agency by which infection is kept alive when penicillin treatment fails in such a condition as osteomyelitis. Since "persisters," when they multiply, give rise to cells which are normally susceptible to penicillin, a therapeutic method akin to tyndallization (intermittent sterilization) is proposed; treatment is to be interrupted in order to permit bacterial growth and thus restore vulnerability. Whatever its other merits, this hypothesis stands or falls according to whether it is true that penicillin acts exclusively on multiplying bacteria. Garrod has examined this question, and contends that neither the influence of temperature nor the death rate in cultures of different ages can be interpreted in support of Bigger's hypothesis. On the other hand there is evidence that the presence of a bacteriostatic agent such as sulphathiazole will interfere to some extent with the action of penicillin. Lest too high a significance should be attached to observations of this kind, it must be remembered that reproductive activity affects the susceptibility of the bacterial cell to other disinfectants for which no such special type of action has ever been assumed, and we do not know whether combination with a bacteriostatic agent would affect them similarly. Perhaps the weightiest argument against adopting the policy of intermittent administration is to be found in clinical experience. In an analysis of causes of failure in penicillin treatment, A. L. Bloomfield, W. M. M. Kirby, and C. D. Armstrong[8] rank the too-early interruption of treatment as a major factor in their unsuccessful cases. Many others have insisted that the attack on infection by penicillin must be relentless and long-continued. He must be a bold man, not to say a rash one, who will deliberately reverse this policy.

NEGLECTED CHILDREN

The new social services to be provided after the war are designed to shower benefits upon the citizen while requiring from him hardly any co-operation beyond the payment of contributions. The encouragement of initiative and enterprise in the individual is not a popular policy. Dr. A. E. Martin, assistant medical officer of Leicestershire, who won the Haldane prize and medal in 1943 with an essay on child neglect,[9] points out the melancholy fact that many families have such grave inherent defects that, no matter what the State may do, their members cannot utilize State-provided opportunities. The problem of child neglect has itself been largely neglected by local authorities, though their existing social and health services cover every house and family in their districts. The success of any scheme for controlling and preventing it must depend first upon an efficient system of finding the neglected children and keeping them under observation. At present the health service, which supervises the child until 5, and the education committee, which is responsible for him after that, often work fair closely together. Almost every case of neglect should l detected by one of them, but the difficulty is that tl various officers have been faced with apparently insolub problems. The work is so sordid and depressing that, no definite scheme exists for calling in help, many childr have not had efficient treatment. As a first essenti according to Dr. Martin, there should be some persc on the central staff of the health authority to whom all cas may be reported, who is available for advice, and wh can give some of his time to the scheme. Normally h would be one of the medical officers. He would be th pivot of the whole scheme. Thus a teacher who suspecte that a child in the school was not properly cared for woul report it as he now reports a child with defective sigh The administrative medical officer would call for a repo on the home conditions from the school nurse or healt visitor. This would stimulate her to pay detailed attentio to the case, and a series of home visits might bring th parent up to the mark. In a more severe case medic inspection could be arranged; the sanitary inspector mig be asked to help on the housing or sanitary side; a medic officer's visit to the home might have a good influenc and, where all else failed, the National Society for the Pr vention of Cruelty to Children might be called in.

The larger part of child neglect is due to a dull or feeb mind in one or both parents. This sets an arduous an never-ending task to the health visitor, who must u the highest qualities of patience, tact, and persistence i educating the mother in household routine, cleanir children, washing clothes, and the rest of the househo duties. When this work is properly done improvement almost invariable. Health visitors are too highly qualifie to be allowed to give much of their time to each famil and more social workers will have to be provided. Fo parents who wilfully or thoughtlessly neglect their childre the inspector of the N.S.P.C.C. must be called into collabo ration. Some authorities are reluctant to do this for fe of destroying the confidential relationship between th health services and the mothers of the district. Muc experience shows, however, that full co-operation an interchange of information can exist without damagir the confidence of the parents. Prosecution is of litt use unless the child has to be removed completely fro the parents' care. The society is better qualified than th local authority to prosecute, and the combination evidence by its inspector and a doctor or nurse of th local authority would form the most helpful basis for mo cases.

The law is at present far from satisfactory, and in th present state of public opinion it would be very har to draft a Bill which would give adequate control ov neglected children and at the same time safeguard th rights of parents. The only certain method of gettir children removed is to produce evidence of really ba conditions at the last visit, but this course can be adopte only after very careful thought. The most importa necessary reform, according to Dr. Martin, is son scheme to bridge the gap between the voluntary supe vision of the society and the cases where children mu be completely removed. A neglected child should l ken away, not because the parent has been convicted ut because its own neglect and suffering have been roved. The local authority should be obliged to look fter children removed for neglect, and such children hould not have to be sent to an approved school. Conerted propaganda addressed to medical officers, directors f education and their staffs, magistrates, and the general ublic would be vital. Such a scheme, Dr. Martin says, ould be inaugurated by circulars from the Ministry of lealth and the Board of Education. Interest in it could e sustained by annual summaries prepared by the medical fficers and published in their annual reports. Dr. Martin ndoubtedly exposes a serious gap in our present social ervices which will have to be closed, at any rate in part, the new provisions are to bear fruit, and wholly if we re to have a sound and healthy population in the years o come.

THE HEALTH OF LONDON

The interim report for 1943 of the County Medical Officer f Health for London[1] comes to hand almost twelve nonths after the year to which it relates—a circumstance vhich robs its statistics of some of their interest, especially s 1943 was a relatively uneventful year for London comared with the years preceding and following. It will e noted that the infant mortality was a fraction higher, nd the maternal mortality a fraction lower, than in 1942, nd that among infectious diseases cerebrospinal fever ontinued to decline; diphtheria had only one-quarter of ts pre-war incidence; dysentery increased, though enteric ever, a disease spread mainly by the same channels, was lmost negligible; scarlet fever was more prevalent than n recent years, and of somewhat heightened virulence; and neasles at one point threatened to assume epidemic proporions. Notifications of tuberculosis increased, though the umber of deaths remained about the same. The only pidemic disease which caused real anxiety was influenza. Iere the number of admissions to the L.C.C. hospitals ose steeply at the end of the year, and recollections of he devastating epidemic of 1918–19 were stirred; but by he end of January, 1944, the incidence had fallen to the easonal normal.

The school medical service returns show that the condiion of London children in the third and fourth years of var was in some respects better than in the pre-war year f 1938. The proportion of children in whom an unsatisactory state of nutrition was found in 1938 was 6.6%, nd this had been reduced in 1942 to 6.2%, and in 1943 o 6%. The proportion of children with defective vision nd of those with adenoids and enlarged tonsils declined otably, and the only outstanding increase was in the umber of children found with obvious decay of the teeth. t should be added that the children inspected by dental urgeons are spread over all ages, and are not confined, s are the medical inspection returns, to the four routine ge groups. The number of children examined, on which e percentages are based, was little more than half in the ecent years what it was in 1938. An interesting comparion is given in the report concerning the trend of infant ortality in London and in New York during the present entury. The New York figures have always been better an those of London. In 1900 the infant mortality in ew York was 135 per 1,000 births, and in London 159, nd the figures in 1943 were 30.2 and 50.7 respectively. The decrease in the deaths of infants, especially since 1935, has been more pronounced in New York than in London—a fact not wholly explained by war conditions in the latter city, and calling for further investigation. From a list of causes of infant deaths it appears that there has been a much greater reduction in mortality from gastro-enteritis and respiratory diseases in New York than in London during the last forty years, and especially during the last decade, and the death rate from miscellaneous causes, but particularly infective and parasitic diseases, injury at birth, and lack of care of the newborn, is more than twice as high in London.

The history of the last war has been repeated in the continued fall in the number of mental patients in L.C.C. institutions. An attempt has been made at St. Ebba's Hospital to assess the value of electric convulsion therapy and insulin therapy given to patients. Of the first 100 female depressive patients who were treated with electric convulsion therapy 87 were cured of their depression, of whom 74 were discharged; the other 13 had for various reasons to be detained; 13 of the discharged patients relapsed and had to be given further treatment. Of 72 female acute schizophrenics who were given electric convulsion therapy and insulin, treatment had been completed in 64 cases at the time of the review, and of these 64, 56 had recovered sufficiently to return home. Similar results were obtained in certain groups of male patients.

The year 1943 saw the introduction by the Council of miniature mass radiography, the unit beginning its operations at St. Luke's Hospital, Chelsea. Up to the time of the report 13,334 miniature films had been taken, and among these 433 revealed some significant abnormality requiring large films to be taken. Of the large films 110 showed pulmonary lesions calling for investigation, 30 showed cardiovascular lesions needing investigation, 155 showed calcified and other lesions in which further investigations were not necessary, and 94 showed no abnormality. The examinees have been factory and office employees, civil defence personnel, and children in secondary schools in the neighbourhood of the hospital. In all cases in which evidence of disease was found the patient's doctor was communicated with, and the *x*-ray film and report were forwarded to him.

HEALTH RESEARCH IN INDUSTRY

In the early days of the last war munition workers laboured very long hours in an effort to make good a shortage of shells, but their output fell and sickness and fatigue increased. This failure to meet the needs of a modern army at war led to the appointment of the Health of Munitions Workers Committee, who were to advise the Government on matters affecting the health and efficiency of those in munition factories. This was the first attempt in this country to investigate scientifically and comprehensively the effects of conditions of work on health. This Committee was succeeded by the Industrial Fatigue Board (later the Industrial Health Research Board of the Medical Research Council), which, by its terms of reference, had opportunity to study all classes of industrial work. But with the return of peace and unemployment the Board had little encouragement from industry. Nevertheless, it survived the rigid economies of 1924, to flourish once again with the revived stimulus of war.

The story of the Board's present activities is told in a report issued this week of the proceedings of a conference held last September.[1] In 1942 the Medical Research Council reconstituted the Board and gave it new terms of reference, to include the whole subject of industrial medicine and disease. In May, 1943, the M.R.C. set up a new Department for Research in Industrial Medicine at the London Hospital, and under Dr. Donald Hunter its staff are energetically investigating both the old and the new toxicological hazards with which industry has to contend. But these are problems confined to specific industries. It is therefore encouraging to know that the combined efforts of this new department and others at the London Hospital are being given to a study of the widespread problem of rehabilitation and resettlement. At Cambridge the M.R.C. has established a Unit of Applied Psychology, where more fundamental research is being done on fitting the man to the job and the job to the man. Besides these two units there remain those carrying out equally important but less dramatic investigation into sickness incidence, methods of dust sampling, and the many problems associated with the heating, ventilation, and lighting of workplaces.

[1] *Health Research in Industry.*, Industrial Health Research Board, M.R.C. H.M.S.O., 1945. (6d.)

Industrial health research must be closely linked with other types of medical and sociological study directed to the health and welfare of the man at home as well as at his job. It must link up, too, with management, the worker, and Government Departments concerned with the health of those in factories, mines, transport services, and offices. There must be facilities for determining the toxicity of various compounds before they are used in production. A wider view of the problem of the worker and his environment should bring together research workers, town planners, and industrialists to prevent the increasing loss of greensward, and the pollution of land, water, and air with industrial effluents. "It is not necessary for the physical appearance of industry to be that of an abomination standing where it should not." A move in the right direction is being made. Departments of Industrial Health have been established at three universities in industrial cities, and close contact between these and other departments of the university, local industries and medical practitioners, the M.R.C.'s Industrial Health Research Board, and the Factory Department of the Ministry of Labour will yield handsome dividends of knowledge. Sir Edward Mellanby has said: "Research can only be a spearhead, and a spearhead without a shaft and without somebody to hurl it is no good whatever." The shafts are the industrial medical officers and technicians. But the whole weapon can be hurled with effect only by an enlightened industrial community.

ASSISTANTS AND LOCUMTENENTS UNDER THE "PAY-AS-YOU-EARN" SYSTEM

It has for many years been the accepted practice of the Inland Revenue Department to regard locumtenents as exercising their profession in a particular way, and not as "employed" by the doctor in whose practices they worked from time to time. The result was that they were regarded as assessable to income tax under the rules of Schedule D and not of Schedule E, and that result was not only convenient to both the parties concerned but was more equitable inasmuch as it gave the locumtenent the normal Schedule D basis on which to claim professional expenses (including agency fees, travelling costs, etc.), of which he would have been unfairly deprived if he had been held to the very strict and limited basis applicable under Schedule E. The introduction of the "pay-as-you-earn" system led apparently to some misunderstanding of the view taken by the Revenue, and in order to clarify the position the matter was raised with that Department by the Northern Branch of the British Medical Bureau. In a letter dated Nov. 27, 1944, the Inland Revenue have stated their view as follows:

"With reference to your letter of Nov. 3 and the previou correspondence I am to say that a doctor who takes a serie of engagements in each of which he acts as a deputy for doctor practising on his own account is, in the view of thi Department, assessable under Case II of Schedule D of th Income Tax Act, 1918. If it is established that he is so asses able any short-term appointment which he may take—fc example, a substitute for an absent assistant or in a hospita —will be included in the Schedule D assessment, and n question of deduction of tax under pay-as-you-earn will aris

"A doctor who is employed as assistant is, however, in th view of this Department assessable under Schedule E, eve though he may change his job frequently.

"Tax should therefore, as a general rule, be deducted unde the pay-as-you-earn system from payments made by a docto to an assistant, whatever the length of his engagement. Ta should not, however, be deducted from payments made t a locum unless he produces a Form P45 showing the pay ments made to him and the tax deducted therefrom in previou weeks of the year."

It is understood from the last paragraph that it is alway incumbent upon the principal to deduct tax under P.A.Y.E where he engages a doctor as assistant; but, where th principal engages a doctor to act as his deputy, the prin cipal is not required to deduct tax unless the locumtenen produces a Form P45. The statement as a whole appear to be clear and satisfactory, but there are one or two point to which it may be desirable to refer. In the first plac the line of distinction between locumtenent and assistan may not always be clear. For example, an individua engaged as a locumtenent may stay on assisting in th practice, even becoming eventually a partner in the firr Clearly all such cases must be dealt with on their ow facts and preferably in consultation with the Inspector o Taxes. Secondly, there may be a little practical difficult where a doctor ordinarily working as a locumtenent take temporary duty as an assistant to, rather than as th deputy of, the local practitioner. What should the latte do in such circumstances? His appropriate action wil depend on the manner in which the locumtenent's (i.e., i the hypothetical case his "assistant's") income-tax affair are dealt with—and that is a matter outside his knowledg The most effective means of overcoming such a difficult seems to be for the locumtenent to notify his own Inspecto of Taxes on the infrequent occasions when he is on th point of acting as an "assistant," requesting him t authorize his "employer" *not* to apply the "pay-as-you earn" procedure in his case. Lastly, errors and oversight are apt to occur in any arrangement into which the huma element enters. What should be done if in fact tax i deducted from the fees or salary in such circumstance that a refund by the "employer" is impracticable? W presume that on the Inspector of Taxes being informe of the facts it would be arranged that credit would b given against the tax payable on the locumtenent' Schedule D assessment for the amount by deduction fr him under "pay-as-you-earn," or alternatively that th latter amount would be repaid by the Revenue as havin been deducted unnecessarily.

We much regret to announce that Sir Henry Gauvai M.Ch., F.R.C.S., medical superintendent of Lord Mayo Treloar Cripples' Hospital and College, Alton and Haylin Island, since its foundation in 1908, died on Jan. 1

Major-General Sir Ernest Cowell, C.B., D.S.O., has ju been appointed Principal Medical Officer to the Healt Section of the Control Commission for Germany (Britis Elements).

Reports of Societies

NUTRITIONAL RÔLE OF MICROFLORA IN THE INTESTINES

A conference of the Nutrition Society was held on Dec. 30 at the London School of Hygiene and Tropical Medicine, Dr. W. R. Wooldridge presiding, to discuss the nutritional rôle of the microflora in the alimentary tract.

The papers at the morning session were mainly concerned with the nutrition of ruminants. Dr. A. C. Thaysen suggested that the value of the bacteria present in the rumen should be ascribed not only to their ability to break down cellulose but to the nutrients derived from the digestion of the bacteria themselves after their passage from the rumen into other regions of the intestines. Mr. Frank Baker, describing technique for the study of the bacterial population of the rumen, said that in his view pure cultural methods gave an inadequate picture, and direct microscopical observation of the micro-organisms present in their natural habitat was necessary. Dr. J. A. B. Smith discussed the formation of protein from non-protein sources of nitrogen, such as urea or ammoniated beet pulp; these materials might replace some of the protein in the diets of cows without serious interference with the production of milk or meat. It appeared that the bacteria of the rumen used the urea or ammonia as a source of protein, and were themselves digested in other parts of the intestinal tract. Mr. M. H. M. Arnold considered that more crucial tests of the value of urea should be made by giving it to cows receiving a diet low in pre-formed protein, and Sir Jack Drummond, Scientific Adviser to the Ministry of Food, asked for reassurance that the urea would not pass into the milk.

Bacteria in the Synthesis of Vitamins

During the afternoon session Dr. S. K. Kon of the National Institute for Research in Dairying, reviewing our knowledge of the part played by bacteria in the synthesis of vitamins in animals and human subjects, recalled that nearly 30 years ago the South African workers Theiler, Green, and Viljoen had concluded that the vitamin requirements of cattle were so low that they might be "covered indirectly by synthesis carried out by the extensive bacterial flora of the intestines." Eleven years later Bechdel and his colleagues in America showed that heifer calves could grow to maturity and reproduce on a diet which contained insufficient vitamin B to support growth in young rats for more than 2 to 4 weeks. When food was removed by means of a fistula from the rumens of cows which had subsisted for three years on the deficient diet, the partially digested material was now found to be a good source of vitamin B for rats. A bacterium of the genus *Flavobacterium* was, moreover, found in the rumen in profusion, and, when isolated and grown on a synthetic medium, proved to be a potent source of the vitamin B complex. Later experiments by other workers indicated that this bacterium and other microflora might be responsible for the synthesis of vitamin B_1, riboflavin, vitamin B_6, nicotinic acid, pantothenic acid, biotin, and vitamin K. Vitamin A was not synthesized, and must be included either as the pre-formed vitamin or as carotene in the diet of herbivora no less than of other animals. An interesting point had emerged in the study of the nutrition of ruminants in the first few weeks after birth. Until the characteristic bacterial flora was established the young animal must depend on exogenous supplies of the vitamin B complex. Thus nicotinic acid had been shown to be essential in the diet of very young calves.

There was ample evidence, Dr. Kon said, that the intestinal bacteria of ruminants were not alone in their ability to synthesize vitamins. A number of workers had demonstrated the presence of the vitamin B complex in the excreta of birds and of non-ruminant mammals, even when they were subsisting on a diet deficient in these vitamins. Recent work by Thompson had shown that *B. proteus vulgaris* could synthesize all known members of the vitamin B complex. Other intestinal organisms—*B. coli*, *B. lactis aerogenes*, *B. faecalis alcaligenes*, and *B. mesentericus vulgatus*—manufactured at least biotin, riboflavin, vitamin B_1, and nicotinic acid, while *B. coli* also produced vitamin K. In spite of the activities of these organisms, however, rats had been used successfully for 30 years in the estimation of several members of the vitamin B complex. It was obvious, therefore, that under normal circumstances the bacteria survived in the intestines or escaped into the faeces without, as in herbivora, yielding up all their vitamins to their host. The coprophagic habits of the rabbit might be significant. As found by Morot 60 years ago, and recently confirmed by Eden and others, this animal passed two types of faeces: during the day the faeces were hard and consisted of more or less completely digested food debris; at night the motions were soft, rich in protein, and swarming with bacteria. Unless precautions were taken these soft faeces were seized and swallowed by the rabbit direct from the anus. It seemed very probable that they represented an important source of the vitamin B complex.

"Refection"

Although rats could not usually subsist on diets deficient in the vitamin B complex unless they were allowed access to their faeces, they might sometimes grow and thrive if starch was included in the diet. This phenomenon, known as "refection," was first observed by the Danish worker Fridericia in 1926. A young rat, which hitherto had been losing weight on a diet deficient in vitamin B, suddenly picked up and began to grow at a normal rate. This change coincided with an alteration in the faeces, which were no longer dark brown and compact, but white and bulky through the presence of undigested starch. Further cases of spontaneous refection were soon reported from other laboratories. It was found that the condition could be transferred to other rats by allowing them to eat faeces from an infected animal. Dr. Kon said he had found that spontaneous refection occurred more often with potato starch than with rice starch. He thought that refection was not due to a specific organism, but that the presence of undigested starch and of the requisite starch-splitting organisms in the caecum led to vigorous fermentation and an acid *p*H, which favoured the formation of vitamins. Even in rats which had not "refected," however, it seemed probable that although the intestinal bacteria did not provide adequate supplies of all vitamins they at least made substantial contributions in some instances. This must be inferred from the need for additional vitamins in the diet when the bacterial activity in the intestines was suppressed by such drugs as sulphaguanidine and succinyl sulphathiazole. The vitamins affected included nicotinic acid, "folic" acid, biotin, vitamin K, and vitamin E, although we had no other evidence that vitamin E was synthesized by bacteria.

Experiments on Human Subjects

Summarizing recent work on the place in human nutrition of the synthesis of vitamins by the intestinal bacteria, Dr. Kon said that Oppel had shown that in human subjects on a uniform diet the amount of biotin excreted in the urine and faeces might be three to six times greater than the intake. In an extensive investigation by Najjar and Holt into vitamin B_1 nine adolescent males were given a basal ration free from the vitamin. At first small supplements were given, which were gradually reduced until the subjects had subsisted for some months on intakes of only 0.1–0.2 mg., as compared with the normal requirement of 1 mg. At this stage no clinical or laboratory symptoms of deficiency were noticed, except that the amounts of vitamin excreted in the urine were very low. When vitamin B_1 was omitted altogether four of the men developed definite symptoms of deficiency, including neuritis or oedema associated with anorexia and sometimes vomiting, within the following three to five weeks. In one man the symptoms were questionable, but the remaining four volunteers showed no sign of deficiency during seven weeks' observation. While only traces of vitamin B_1 were found in the faeces of those who showed signs of deficiency, much larger amounts were found in the faeces of those who had remained free from symptoms. The ability of the large intestine to absorb vitamin B_1 was demonstrated by a marked rise in urinary excretion after the injection of the vitamin per rectum. When one symptomless subject was given succinyl sulphathiazole the faecal output of vitamin was promptly reduced. Similar experiments by the same authors had suggested that riboflavin also was synthesized in the alimentary tract. Ellinger, Coulson, and Benesch had found that the amount of nicotinic acid excreted by the human subject was often greater than the intake, and that the excretion was reduced after the administration of succinyl sulphathiazole. The pellagra-producing properties of maize might be due to its bad influence on the bacterial flora, since it was no worse than wheat (white flour?) in its content of nicotinic acid. Conversely the alleged ability of milk—a poor source of nicotinic acid—to prevent pellagra might be due to its good effect on the flora.

Dr. L. J. HARRIS, describing refection in rats in his laboratory, said that in the estimation of vitamin B_1 in bulky food materials the bradycardia method had the advantage of being very rapid, and thus did not allow time for the intestinal flora to be affected. Prof. FRIDERICIA mentioned that the starch recovered from the faeces of refected animals had recently been found to be less readily digestible than the original material.

Sir JOSEPH BARCROFT, F.R.S., recounted how, to confound sceptics, he had actually isolated 300 ml. of acetic acid from the intestines of a dead horse. Acetic acid was rapidly metabolized in a heart preparation perfused with Ringer's solution. In all herbivora about one-sixth of the digestible carbohydrate appeared to be converted to volatile acids in the course of metabolism. Dr. JAMES STEWART referred to the early work of Kellner, who had shown that, weight for weight, cellulose was about equal to starch in nutritive value. The symbiotic action of the bacteria of the rumen was therefore most efficient. The CHAIRMAN, in summarizing the proceedings, said that further work seemed desirable on the species of bacteria which were beneficial to their host. The influence of diet on the intestinal flora, and even on configuration of the alimentary tract itself, was an interesting subject. Thus it had been stated that the Russians, who were accustomed to bulky food, had large intestines of much greater capacity than those of the people of this country.

Correspondence

Health of Children in Wartime Day Nurseries

SIR,—Wartime day nurseries have now been open for some years, and doctors and nurses throughout the country have had an exceptional opportunity of observing the effect of a community life upon the health of these young children. Is it in the main a beneficial effect? Opinion seems to be divided, and there is little recorded evidence. May we therefore ask the hospitality of your columns to make known a scheme of research work which is being organized by the Medical Women's Federation into the health of children in wartime day nurseries compared with children of similar ages not in nurseries. The scheme falls into two parts. One part comprises an investigation by a whole-time clinician covering a comparatively small number of children but extending over a period of a year. This work is already being carried out by Dr. Margaret McLaughlin, on behalf of the Medical Women's Federation, in Birmingham, and we are greatly indebted to the medical officer of health and his staff in that city for making it possible to undertake this work. In the second part it is intended to compare the results of a single examination (relating especially to the evidence of respiratory infection) of a much larger number of nursery and non-nursery children throughout the country. For this the Federation will seek the co-operation of medical officers of health in many areas.

The purpose of the investigation is to obtain evidence which may have a bearing on the value of day nurseries, at least in so far as the health of the children is concerned, and which to that extent may be of assistance in determining future policy regarding day nurseries.—We are, etc.,

JANET M. CAMPBELL,
President, Medical Women's Federation.

73, Bourne Way,
Hayes, Bromley, Kent.

KATHERINE M. HIRST,
Chairman, Day Nursery Committee.

Episiotomy

SIR,—The article by Dr. J. D. S. Flew (Nov. 11, 1944, p. 620 and the subsequent correspondence are apt to be construed a an invitation, or even an exhortation, for the wholesale practic of episiotomy. If this procedure becomes almost a routin it can only add to the already ample, and seemingly inevitable damage which results from childbirth.

I have no wish to offer carping criticism, and I feel sur Dr. Flew will absolve me from any such intention when while agreeing with much of what he says, I maintain tha his indications for episiotomy are too wide, and, moreover, are not convincingly supported by his figures. Apart from the "tone of the vaginal walls," why advocate episiotomy in the 58 cases out of 135 (a worth-while percentage) in which i was not found necessary? A torn perineum with a lacerated vagina is a nasty, unsatisfactory result, too often the finale of bad obstetrics and much to be condemned; but proportionately satisfactory, and the ideal often attainable, is the well-conducted normal primiparous confinement leaving an undamaged woman showing, two months later, practically no signs of childbirth.

I believe that few will subscribe to the idea of midwives carrying out this procedure at their discretion, even after special training. The most experienced can err in his judgment and make mistakes of omission or commission. The diagnosis of undue delay and its causation is often difficult; the arrival of the head on the perineum is not signalled in unmistakable fashion, nor is any satisfactory standard of measurement of uterine contraction possible. I know that these indications are not intended to be taken too literally, but one shudders at the possibilities envisaged if their interpretation were given to an even wider field than at present.

One other statement needs very conservative acceptance: the paraesthesia of the stretched perineum is very variable and has always been exaggerated. Even now one hears that "they even cut me before I got the chloroform." No episiotomy should be performed without adequate anaesthetic, nor is there ever need or excuse for so doing.

The importance of repair is rightly stressed by all; accurate apposition is essential for restoration of function and to avoid future discomfort. Particularly, as regards the latter, is this so at what will be the edge of the future introitus, where painful tags or scar are most likely. The vaginal floor is comparatively easy to suture correctly, but not so the perineal skin, especially as it nears its junction with vagina, and I need quite often to remove these stitches on account of puckering and begin again.

I would like to offer two methods which greatly facilitate the repair of an episiotomy. During a contraction, with the perineum stretched, make three or four transverse scratches with a needle, the first close to the mucocutaneous junction, covering the area to be incised. When it comes to sewing up, the needle is inserted and brought out in the line of each scratch mark successively; if the first skin stitch at the mucocutaneous junction is used to exert traction the remaining marks will be emphasized, and complete accuracy results. (No originality claimed.)

A second method is a little more bothersome. Hold the perineum on the stretch with two fingers in the vagina, insert the stitches between contractions before incising, clip the free ends, pass a narrow metal spatula under the loops on the vaginal floor, as a form of protecting guide, or produce them externally, and incise. A little practice soon obviates the annoyance of cutting the catgut loops, and the stitches can be tied directly the second stage is completed, thus avoiding any prolongation of the anaesthetic. Additional stitches are very easily inserted if required.

On the question of the anaesthetic, while any method can be made successful, I think that local analgesia should be reserved for the rare occasions when the attendant is without assistants of any sort. Less handling, less possibility of sepsis in an already injured tissue, less discomfort to the patient, and more freedom of action resulting in greater efficiency are my reasons for advocating general anaesthesia whenever possible.—I am, etc.,

London, W.1.
F. NEON REYNOLDS.

Hypoproteinaemia during Recovery from Anaemia

SIR,—At the commencement of his article on hypoproteinaemia during recovery from severe anaemia (Jan. 13, p. 45), Dr. Trevor Davies writes: "Generalized oedema due to diminution of the serum proteins is not a common complication of the treatment of anaemia . . ."; and at the beginning of his comment he writes: "The above case illustrates the importance during the treatment of severe anaemia of maintaining a diet rich in protein."

In 1942 I published an article on the prevalence of hypochromic anaemia in the adult population. It may be of interest that since that time I have treated many cases of hypochromic anaemia with haemoglobin between 50 and 65% of normal, but I have never seen oedema either before or during treatment. I have treated groups of cases with ascorbic acid, vitamin B complex (B_1, B_2, B_6), and vitamin A, but in no group did the administration of vitamin have any influence on the Hb%. However, one invariable result of the administration of ascorbic acid (200 mg. per day) was an immediate and progressive increase in the number of red cells, without any effect on the Hb%. Finally, in no case of hypochromic anaemia have I found any diminution in the serum albumin or serum globulin either before or during treatment.

It seems probable that the condition, which continues to be prevalent in young adults of both sexes, is due to deficient intake of iron, but the deficiency is probably due to the low consumption of meat, and not the low consumption of vegetables as used to be thought.—I am, etc.,

London, S.E.24 KENNETH MCFADYEAN.

Bilateral Tuberculous Pleural Effusion

SIR,—Major Peter Kerley[1] states that double effusions are rare in tuberculosis, and Prof. Bruce Perry,[2] in his very interesting Bradshaw Lecture on the aetiology of erythema nodosum, states that a bilateral effusion is "an unusual occurrence with tuberculous effusion." This does not mean that bilateral exudative pleural effusion is rarely tuberculous, but may easily be so interpreted unless a clear warning is given.

Our experience of bilateral tuberculous pleural effusion at Sidcup can only be very briefly summarized here, and probably merits more detailed analysis, as the alleged extremely serious prognostic significance of bilateral effusions[3] [4] has not been confirmed in this unit. Of a consecutive series of 601 notified cases of pleural effusion, 319 male and 282 female, 35 were bilateral, of which 17 were male and 18 female. With an incidence of nearly 6% it appears that even the statement that double effusions are rare in tuberculosis needs correcting.

In our series of 601 cases a history of erythema nodosum has been obtained only 15 times (2.5%), of which cases 10 were female and 5 male, with an age grouping between 15 and 29 years and a maximum incidence around 21 years. All these cases were strongly Mantoux-positive with a dilution of 1:10,000. In 6 cases there was an interval of about a year between the erythema nodosum and the onset of the pleural effusion.

A history of erythema nodosum is probably best elicited by asking every patient if he has had "rheumatism with red lumps on the legs" (it was a pleasure to read that in the San Joaquin Valley the people call erythema nodosum "the bumps"!), as patients have so often been told by their doctors that they have had rheumatism. So much does the "rheumatic" aetiology stick that in 1944 a boy of 18 years was subjected to tonsillectomy a few weeks after an attack of erythema nodosum in spite of a skiagram showing a grossly enlarged right hilum; he then developed a right pleural effusion and subsequently bilateral pulmonary tuberculosis, with positive sputum.

A useful investigation in cases of doubtful aetiology is the antistreptolysin titre, which will invariably be high in streptococcal cases; this investigation can easily be performed, while intradermal streptococcal tests are not readily available.

One final point: the Scandinavian authors have clearly shown that erythema nodosum is usually an *early* manifestation of tuberculous infection. This, although true in the majority of cases, is not always true. Two of my own cases prove it.

1. A girl aged 17 had been treated at the age of 8 for tuberculous glands of neck, developed erythema nodosum 8 years later, and after a further 12 months a tuberculous ascites and right pleural effusion.
2. A boy aged 18 had a laparotomy in April, 1944, for tuberculous ascites, then developed a left pleural effusion in July; tuberculin patch test was then possible. In November a cold abscess presented above the pubis and was found to originate from the right sacro-iliac joint. He had two crops of typical erythema nodosum before being transferred to a special orthopaedic unit. A skiagram of the chest showed complete resolution of the pleural effusion and clear lung fields. Antistreptolysin titre of serum was 30.

I wish to thank Dr. R. L. Quilliam for placing at my disposal some of his case notes. I also thank Sir Allen Daley and Dr. Ellingworth for permission to publish the figures.—I am, etc.,

Queen Mary's Hospital, Sidcup, Kent. E. MONTUSCHI.

Nursing and Tuberculosis

SIR,—After reading Dr. Esther Carling's letter (Jan. 13, p. 59) it occurred to me that a useful investigation would be a tour of hospitals by a mobile mass radiography unit, and the nursing personnel filmed, those with suspicious films to be followed up in the usual way. This would establish the incidence of pulmonary tuberculosis in nurses, and a comparison could be made: (*a*) between general hospitals and hospitals for tuberculosis; and (*b*) with the general population. Certainly many of the factors that cause a breakdown with pulmonary tuberculosis are present while a student nurse is being trained.

In the same issue of the *Journal* Dr. Grenville-Mathers draws attention to the frequent failure to investigate home contacts of cases of pulmonary tuberculosis. I agree, and would add that the nursing personnel of sanatoria are contacts as much at risk as home contacts, and therefore should be re-examined and *x*-rayed periodically.—I am, etc.,

R. WRIGHT,
Coventry Medical Officer, Sterling Metals Ltd.

A Treatment for Superficial Eye Infections

SIR,—Wartime conditions, mainly "black-out" and working in a confined atmosphere, have created an increase in superficial eye affections. These excessive conjunctival vessel dilatations are painful, leading to worry and apprehension both to the patient and to his fellow workers, and absence from work.

The use of a solution of 1% natural ephedrine hydrochloride is not frequent in eye-drops, but I have found it useful to bring about decongestion of the conjunctival vessels. To this ephedrine solution can be added a weak solution of silver vitellinate, and enough sodium chloride to make the drops practically equivalent to normal saline. It is difficult to avoid the formation of silver chloride, but if the conjunctival sacs are irrigated afterwards with warm water from an undine the possible onset of argyrosis is reduced to a minimum; if a stable solution of the three above-mentioned components can be obtained the risk of argyrosis should be *nil*.

With the combined action of a decongestive and an antiseptic the eye is irrigated and disinfected simultaneously, while the patient gets early relief and is enabled to return sooner to work.—I am, etc.,

London, W.1. GRAYDON HUME.

Spinal Analgesia in Penetrating Abdominal Wounds

SIR,—I was much interested to read in your issue of Dec. 9, 1944 (p. 769), Major R. Binning's defence of a method of anaesthesia which I had hoped all careful and prudent surgeons and anaesthetists had long ago discarded. His assertion that it was the fact that a spinal anaesthetic was used in the case reported and not the Etherington-Wilson method of giving it which was the cause of death I most definitely refute. Although it is frequently taught that spinal anaesthesia is dangerous in cases of the acute abdomen, if properly used—as he can confirm any time he chooses to visit the Manchester School—it is perfectly safe. There is no doubt whatever that the technique in the case quoted was the cause of death, as the analgesia had reached the lower cervical segments before respiratory paralysis occurred.—I am, etc.,

B.N.A.F. THOMAS MOORE.

Parotitis from Unusual Duct Obstruction

SIR,—I read the account of an interesting case of parotitis by Dr. R. H. Trinick (Jan. 6, p. 13). The following case of acute simple parotitis due to an unusual type of duct obstruction may be worth recording.

On Jan. 9, 1944, the patient, a male aged 55, attended the dental surgery at the West Riding County Mental Hospital, near Huddersfield. There was a large hard swelling of the left cheek which was causing a considerable amount of pain. The condition had been present for a week and was gradually getting worse. The left submaxillary lymph glands were enlarged and tender, and there was some difficulty in opening the mouth.

Examination of the teeth of the left side revealed no advanced caries. There was no inflammatory condition of the gums. A small amount of pus was noticed on the inner aspect of the cheek opposite the maxillary first molar. This was swabbed away, when the opening of Stenson's duct was seen to be enlarged and surrounded by a small zone of inflammation. I then noticed what appeared to be a small foreign body lying in the opening of the duct. Attempts to swab this away failed, and, on grasping the "foreign body" with a pair of dressing tweezers, a grass stalk of length approximately 2½ in. was removed from the duct. This was followed by the discharge of a small quantity of thin, yellow, fetid pus.

Irrigation of the mouth with a mild antiseptic solution was advised to keep the enlarged duct opening free from debris. The patient was seen again one week later. The swelling and pain had disappeared and the inner aspect of the cheek was quite normal in appearance.

It is remarkable that a stalk of grass of length 2½ in. could become completely embedded in the parotid duct, which has an average length of approximately 2 in. My thanks are due to Dr. D. K. Bruce, medical superintendent of the hospital, for allowing me to report the case.—I am, etc.,

Huddersfield. EDWARD I. FRIEND, B.CH.D., L.D.S.

Artificial Insemination

SIR,—I am distressed at the unrealistic attitude shown by many of your correspondents on this subject (copies of the *Journal* reach me two months late). Surveys before the war by Cattell and by Fraser Roberts showed that our national failure to reproduce was greatest among those who were above the average in their hereditary endowment for intelligence. For the past eighteen months I have been watching and doing my best to minimize the tragic preferential destruction of some of our best types—young officers and N.C.O.s of front-line infantry battalions. A similar selectively high death rate of the fittest, most courageous, and most intelligent is occurring in the other Services.

Soon this country will face a desperate shortage of types capable of leadership and of producing intelligent answers to novel and difficult problems. Temporarily we may tide over the crisis by ensuring that every child who has outstanding genetic potential gets the environmental chance to develop this potential. But this is living on genetic capital, and the future of our country depends on the rapid provision of new children born with high genetic potential for intelligence and other desirable qualities.

First and foremost, married couples who are themselves above the average must plan the size of their families to be above replacement level and above the average of the community. If, as Mr. Churchill thinks, the average couple should aim at four children, then the above-average must plan for six to eight. Secondly, "artificial insemination" should prove a most useful supplementary method of producing children of high genetic potential, since the male donors can be specially chosen for their superlative genetic endowment; for qualities where inheritance is by multiple genetic factors, as for intelligence, such children will have an endowment midway between that of the mother and the exceptional donor.

Artificial insemination should be used chiefly in two types of case. (*a*) Where a woman is unable to find a husband—there will be a considerable surplus of women over men of reproductive age after the war. In particular there will be numbers of young widows of good type, who have only been able to have one or two children before their husbands wer killed. It is greatly in the national and their own interest that these women should have further children, at least up to the level of four, which would be replacing themselves and their dead husband. (*b*) In cases where the husband is sterile or should not father children for eugenic reasons, and both husband and wife prefer artificial insemination to the adoption of children. The use of a man's own sperms artificially to inseminate his wife when there is mechanical difficulty or relative insterility is clearly dangerous unless it is certain that the disability is not inheritable.

I am not competent to pronounce directly on the ethics of the matter; but ethical beliefs are subject to natural selection according to the survival rate of those who hold them. A group or country which fails to avail itself of the possibilitie of artificial insemination will have a correspondingly lowe survival rate.—I am, etc.,

C. O. CARTER.

SIR,—The unimpassioned article on the practice of artificial insemination by Dr. Mary Barton, Mr. Kenneth Walker, and Dr. B. P. Wiesner (Jan. 13, p. 40) has come at a most timely moment. This is a straightforward procedure to be practised after due consideration on selected cases. One point, however deserves further consideration—the registration of the birth of a child resulting from donor insemination (A.I.D.). In this matter I, too, have sought and quote eminent counsel's opinion: "In my view any husband or wife or medical practitioner who knowing of the impotence or non-access of the husband, and knowing that the practice or operation of artificial insemination had been resorted to, wilfully gave information, etc., to the registrar that the husband was the father of the child conceived would commit an offence under the section. In the case of a title or inheritance being involved, questions of fraud or conspiracy to defraud the heir or other person entitled might well arise. In my opinion the only proper way to register the birth of a child conceived by artificial insemination is by leaving the columns for the name and other particulars relating to the father blank, whatever may be the subsequent embarrassment to the infant."

The advice, it will be seen, differs from that in the article, and, the possibility of disputed inheritance not being remote, it is the advice I give.—I am, etc.,

London, W. REYNOLD H. BOYD.

Deaf Aids

SIR,—It has recently been announced in the press that a Parliamentary investigation is shortly to be made into the subject of deaf aids. Perhaps my experience of these will be of interest and value to your readers.

Suffering from progressive deafness (otosclerosis) I have used aids of various types for more than 20 years, and until the war found these to be of increasing efficiency, especially after the introduction of the valve type of aid. During this time I have only once been the victim of a deliberate "ramp."

At the present time I possess three "aids," all of which *when in working order* are extremely efficient, even in my advanced deafness. The great snags now are keeping them in working order and the very high cost of maintenance. Aids A and B are of the same make, A being purchased shortly before the war and B in 1942. At first both gave excellent service and cost little more than the cost of batteries, as the jelly-type accumulators are charged at home, and a pair lasted two years. Both batteries and accumulators have since increased in price and depreciated in value. Below is a summary of the cost for repair and maintenance of A and B for the years 1943 and 1944.

1943	£	s.	d.
January	5	5	8
February		14	0
April	1	0	8
May		8	0
June		16	0
November	1	7	6
	£9	11	10

1944	£	s.	d.
March	3	0	0
April	4	4	0
November ..	1	9	6
December ..	8	15	1
	17	8	7
1943	9	11	10
Total ..	£27	0	5

Registered postage of instruments has been a heavy charge of which I have no record, nor have I any record of the cost of H.T. batteries, which last about 6 weeks and cost 6s. each (plus postage). Both instruments are carefully handled and in no case was the damage due to violent usage (except in the case of valves damaged during return by post). This high cost seems to be due to the very poor quality of wartime components, the lack of skilled service mechanics, and the impossibility of getting the slightest adjustment made without sending the aid to London and risking postal damage.

In July, 1944, as both A and B were out of commission, I purchased aid C of another make at a cost of £26 5s. This, using only dry batteries, is light, compact, and very powerful, but is much more expensive to run, costing about 7s. a week in batteries only (purchase tax must be paid on some of these). In the four months since purchase four new valves have been required and a new switch. These have been supplied free under the guarantee, but are evidence of the poor material in use. In each case breakdown has meant a journey to Manchester (fare 7s.) and the waste of valuable time. The capital cost of my deafness in two years has been £53 5s. 5d. —maintenance £27 0s. 5d. plus cost of C £26 5s. In addition to this are running costs, of which I am now keeping a record, and the mental wear and tear of frequent breakdowns at most inconvenient times. Though many of these difficulties are due to the war, I feel that the following suggestions would be of help in tackling the prohibitively high cost of combating deafness: (1) The production of a "standard model" aid which could be serviced by any competent wireless mechanic and for which spares could be obtained by local wireless engineers. This would minimize damage in transit and need not interfere with the development of special models by individual manufacturers. (2) The development of light-weight accumulators, preferably of a type able to be charged at home, and of durable batteries. (3) Removal of the purchase tax from all batteries used for deaf aids. (4) Investigation of the possibilities of "all mains" sets, especially for home or office use, at a reasonable cost.

The heavy economic and social burden of deafness can now be greatly lightened for the well-to-do, but for many others expensive aids purchased in hope have had to be abandoned in despair because of the impossible cost of keeping them going.—I am, etc.,

Brierfield, near Burnley. E. M. BARLOW.

The Non-teaching Hospital in Planning

SIR,—In reference to your notice on the formation of an Association of Voluntary Teaching Hospitals (Jan. 13, p. 55) I should like to take the opportunity of stressing the importance of also obtaining comprehensive evidence from the so-called non-teaching hospitals in any planning or negotiations arising from the Goodenough report.

The hospitals without medical schools are responsible through their resident appointments for the practical post-graduate training of the majority of the general practitioners of this country. It would be interesting to know the exact figures, and I think that if these were obtained the result would be surprisingly high. The amount of clinical material available to each resident at these hospitals is usually greater than that available to a junior resident at a teaching hospital. In addition, a relatively junior resident at a non-teaching hospital is afforded greater personal responsibility than at a teaching hospital, and this is invaluable in after-life and equally important as the continuation of academic instruction at a hospital with a medical school.

It has always appeared to me that the value of these appointments has not been fully exploited by the medical profession. At the same time I think that to a certain extent the educational value is vitiated by the fact that the actual amount of work they entail leaves the residents with little, if any, time for concurrent study. The reason is frequently one of understaffing by the boards of management for reasons of finance, since they are naturally not interested in the question of higher medical education, but are only concerned with seeing that the work of the hospital is adequately carried out.

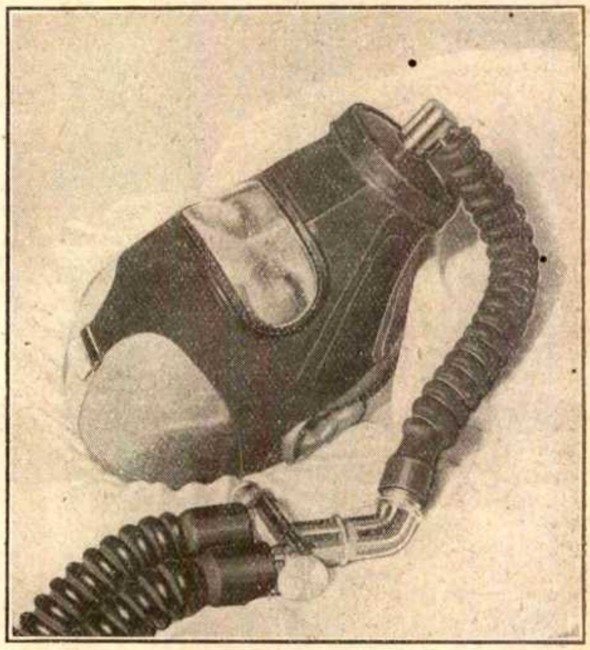
In view of their educational importance I think there should be a proper survey of the conditions of these appointments, and, if possible, a register should be kept by a central authoritative body to which recently qualified men could refer, and which would be a guarantee that the hospitals represented on the register are adequately staffed, allow reasonable time for study, and provide all the necessary facilities. I consider that there should also be some differentiation of these appointments into those which are only suitable for men proposing to enter general practice and those suitable for men wishing to proceed to a higher qualification or gain a special diploma.

In view of the increasing number of medical graduates required, it is obvious that an even larger number of men will have to rely on these hospitals in the near future for their practical postgraduate instruction, and it is important that the best use is made of the vast amount of clinical material available. At the same time more generous staffing—both resident and consultant—of these hospitals would inevitably enhance the standard of work performed and thus benefit the population as a whole.—I am, etc.,

Bournemouth. THOMAS ROBSON.

Civilian Respirator as Anaesthetic Mask

SIR,—Dr. J. Morland Smith (Dec. 23, 1944, p. 820) rightly complained that the Clausen harness often obstructed respiration by depressing the jaw. I have not, as yet, tried his remedy with the wooden tongue depressor, but it has occurred to me that an anaesthetic mask of very similar design to the ordinary civilian respirator would do much to overcome this annoying trouble. At any rate, this has been my impression with a converted gas-mask that I have been using for anaesthetic purposes during the past few months. If the correct size of mask is worn and the tapes are fairly tightly adjusted the jaw is well supported and has little or no chance of falling back throughout the anaesthetic. Furthermore, this type of mask keeps in position much more satisfactorily than the usual face-piece held by the harness, and the patient can be moved from trolley to operating table and into any position on the latter without much fear of the mask becoming displaced. With the gas in the bag at moderate pressure there is no leakage, and, when necessary, the mask can be removed and reapplied with ease and speed.



During the past three months I do not think I have had a single patient object to being so completely covered up, and all have been questioned before commencing the anaesthetic. The mask shown in the photograph is kept firmly attached to the plastic adapter by the elastic band found on the canister, and any size of mask can, if available, be used. To prevent sagging when the tubing is in position, narrow strips of plastic material have been inserted into small rubber sleeves at the sides and in front, below the window.—I am, etc.,

F. S. VAUGHAN,
Hon. Anaesthetist, County Hospital, Bedford.

Action of Eumydrine in Pyloric Hypertrophy

SIR,—In Sir Walter Langdon-Brown's fascinating address (Jan. 13, p. 35) mention is made of a subject that has long puzzled me. That is the use of eumydrine in infantile pyloric hypertrophy. The action of the vagus is generally given as that of an "emptier" and that of the sympathetic as a "filler." Now, as Sir Walter Langdon-Brown says, "atropine paralyses the vagus," and a few lines later that eumydrine, which has an atropine-like effect, is particularly useful in relieving pylorospasm. Surely its only possible action can be in abolishing the peristalsis of the stomach and so diminishing the vomiting. What is wanted is something that will paralyse the sympathetic.—I am, etc.,

Nelson. O. WILSON.

The Services

AMERICAN HONOUR FOR SIR E. M. COWELL

The President of the United States has awarded the military decoration of the Legion of Merit to Major-Gen. Sir Ernest M. Cowell, K.B.E., D.S.O., F.R.C.S., "for exceptionally meritorious conduct in the performance of outstanding services from September, 1942, to March, 1944," as director of medical services at Allied Headquarters, Mediterranean Theatre. General Cowell was responsible for the medical services of the Allied landings and later operations in North Africa, Sicily, and Italy. "He welded together the medical services of the American and British Forces and produced a highly successful organization which resulted in the saving of many lives and contributed to the well-being and comfort of the sick and wounded of both nations." He received the decoration at the hands of General Eisenhower on Jan. 15.

The following have been mentioned in dispatches in recognition of gallant and distinguished services in Italy: Brigs. (Acting) J. J. Magner, M.C., and J. G. Morgan, O.B.E., T.D.; Cols. (Temp.) C. B. C. Anderson, O.B.E., A. Angus, T.D., J. T. McOuat, O.B.E., T.D., R. M. Savege, O.B.E., M.C., C. H. K. Smith, O.B.E., M.C., J. R. N. Warburton, M.C.; Col. (Acting) G. G. Drummond; Lieut.-Col. J. H. Ward, D.S.O., M.C.; Majors (Temp. Lieut.-Cols.) W. A. Ball, T.D., W. S. Brindle, H. A. Brittain, J. D. Easton, O.B.E., W. Graham, L. J. Haydon, L. G. Irvine, D. MacD. Lyon, D. M. Mitchell, W. Patrick, G. W. Molyneux, E. F. S. Morrison, M.C., J. J. O'Connell, O.B.E., J. Pyle, M.C., J. H. Sangster, A. Wilcox, and P. H. Wood; Capt. (Temp. Major) (Acting Lieut.-Col.) N. G. G. Talbot; Major S. S. Chesser; Capts. (Temp. Majors) S. Alstead, A. H. Baker, E. L. Carter, F. A. Denz, J. F. Ford, E. M. Griffin, W. F. Hamilton, W. A. Heggie, M.C., C. C. Hurst, D. B. Jagger, D. Jefferiss, R. C. Little, J. C. MacKillop, B. J. Malley, D. Matheson, J. M. McKiddie, J. D. N. Nabarro, A. I. Ross, H. M. D. Shepherd, N. J. Y. Simpson, A. Stuart, H. Waters, W. R. West-Watson, M.B.E., J. H. Whittles, and E. G. Wright; Capts. H. Auger, E. Batley, O. H. Belam, C. Cameron, J. W. M. Christie, T. B. Davidson, K. B. Dawson, D. C. Devine, G. F. Edwards, M.B.E., J. T. A. Essex, C. Giles, S. J. G. Gilmour, R. T. Grime, A. Henderson, A. W. F. Heron, E. W. Lindeck, J. G. Macarthur, M.C., D. Macdonald, J. McLean, L. F. McWilliams, F. E. Milson, A. E. Rampling, E. M. Sewell, J. M. M. Steven, M. G. Sutton, R. T. B. Watson, C. W. M. Whitty, and M. Wirtheim; Lieuts. C. Creffield, F. B. Lee, and R. C. Medland, R.A.M.C.; Capts. (Temp. Majors) L. N. O'Hara, A. K. M. Mazhar, and V. Parkash; Capts. S. C. Gosh, I. Singh, M. K. Ray, S. Kesavelu, S. K. Misra, and P. N. Swift; Subadar (Acting Subadar Major) H. Narian; Subadars M. K. Choudhury, B. N. Ray, and S. N. Lal; Jemadar B. H. Faroque, I.A.M.C.

The Cross of Merit (with Swords) has been conferred upon Acting Squad. Ldr. P. A Carrie, R.A.F.V.R., by the President of the Republic of Poland in recognition of valuable services rendered in connexion with the war.

CASUALTIES IN THE MEDICAL SERVICES

Died in Italy.—Capt. Michael Robert Mullins, S.A.M.C.

Wounded.—Capt. N. G. D. Campbell, War Subs. Capts. J. H. Bennett, S. M. P. Conway, M.C., J. C. F. Cregan, and J. Scott, R.A.M.C.

Repatriated in September, 1943, now known to be wounded.—War Subs. Capt. N. C. Rogers, R.A.M.C.

Reported missing at Arnhem, now known to be wounded and prisoner of war in Germany.—Major C. J. Longland, R.A.M.C.

Missing.—Capt. B. d'E. Barclay, R.A.M.C.

Prisoners of war.—Lieut.-Col. W. C. Alford, O.B.E., R.A.M.C., Major C. Russell, M.C., R.A.M.C.

Obituary

SIR BUCKSTON BROWNE, LL.D., F.R.C.S.

The death of Sir Buckston Browne at the age of 94 removes a picturesque and attractive figure from his favourite haunts in Marylebone and Lincoln's Inn Fields. He retained a remarkable vigour till the end of his life. Buckston Browne belonged in spirit to a much later age than the mid-Victorian in which he was born, and physically too, for anyone listening to his strong voice and robust utterance would never have guessed his years. When he was 90 he announced his intention of living to be a hundred, and in token thereof renewed the lease of his Wimpole Street house for another ten years. At that same advanced age, after the second European war had broken out, he dismissed with contempt any suggestion that he should go to live in the country, and insisted on taking his usual walks in the "black-out." Within a few weeks of becoming a nonagenarian he addressed a public meeting on great athletic feats he had witnessed in his time, and famous pedestrians and pugilists who had been among his acquaintance. Their achievements he attributed to total abstinence, which he himself had practised for sixty years. His own particular "vanity"—to use a Wellerism which is appropriate with reference to one who was president of the Dickens Fellowship—was snuff, which he took as a prophylactic against colds in the head, but we believe he strictly rationed his allowance by putting the snuff receptacle in a distant part of his house so that some real effort was necessary if he wanted another pinch.

[Photo by Bassano, Ltd.

George Buckston Browne was born in Manchester and educated at Owens College. He was the only son of Dr. Henry Browne, physician to the Manchester Royal Infirmary and lecturer on medicine to the Medical School. Five successive generations of Brownes were doctors, the first of this line being Dr. Theophilus Browne of Derby, fellow-townsman and contemporary of Dr. Erasmus Darwin, grandfather of Charles Darwin, who lived in Derby from 1783 to 1802. George Buckston Browne was the fifth of this dynasty, and his great sorrow was that, having lost his only son, Lieut.-Col. George Buckston Browne, D.S.O., in the last war (he died in 1919), there was no one to follow him in the profession. But he found solace in the fact that his only daughter is the wife of Sir Hugh Lett, Past President of the Royal College of Surgeons.

In 1866, at the age of 16, Buckston Browne matriculated as a student of London University and entered University College, where he was presently awarded medals in anatomy, chemistry, and midwifery, gaining the gold medal for practical chemistry and the Liston gold medal in surgery. He qualified M.R.C.S. in 1874, and was made house-surgeon at University College Hospital, where he served under Sir John Erichsen, then at the end of his term as surgeon there, and was made demonstrator in anatomy under Prof. George Viner Ellis. Later he was invited by Sir Henry Thompson, then consulting surgeon to University College Hospital, with a fashionable practice in Wimpole Street—he had just numbered the Emperor Napoleon III among his patients—to be his private assistant and afterwards his collaborator. He remained in association with Sir Henry Thompson for 14 years in private surgical practice in London, and then for 30 years he practised alone. His application to his profession was so complete that it was said that for 27 years he had neither a free day nor a holiday. When he was quite a young man the Harveian Society, which he joined in 1874, and of which after 50 years he was made Life President, honoured him by asking him to give the Harveian Lectures. The remuneration was not to be despised—15 guineas for three lectures—but the giving of those lectures had an immense effect on whatever success he had met with in his profession as a private surgical practitioner in London. Later in life he showed his gratitude by endowing the annual dinner of the Harveian Society and a biennial prize for essays by young practitioners.

Buckston Browne's Benefactions

The fortune which he acquired by addressing himself zealously to his work he used magnificently in the interests of the profession and of the nation. In 1927 Sir Arthur Keith made an appeal for the preservation of Down House in Kent, where Darwin lived for 40 years and where he died in 1882. Mr. Buckston Browne, as he then was, undertook immediately to make himself wholly responsible for buying the estate and establishing a fund for its upkeep. He acquired the home from Prof. Charles Galton Darwin, grandson of Charles Darwin, and transferred it under the most liberal conditions to the British Association as a national memorial. Certain of the rooms, particularly the old study in which *Origin of Species* was written, were furnished as nearly as possible as they were when Darwin lived in them. He also commissioned the Hon. John Collier to paint replicas of his well-known portraits of Darwin and of Huxley to be hung at Down House, and the house gradually became a repository of Darwinia.

In 1931 Buckston Browne followed this with another splendid gift of £100,000 to the Royal College of Surgeons "for the erection, endowment, and equipment of an institution where problems relating to surgery or the surgical treatment of disease should be investigated by research workers chosen by the College." A surgical research farm was established in the village of Downe, adjoining Down House. The foundation stone of this enterprise was laid by the late Lord Moynihan, who declared on that occasion that Mr. Buckston Browne took his place among those who might be regarded and honoured for all time as "immortal benefactors." In reply Buckston Browne spoke of his happiness in being able to bring the spirit of John Hunter alongside that of Charles Darwin. He also made the remark that when he was a student he could not walk for ten minutes in London without seeing some unhappy person whose face was scarred with smallpox, and now the pock-marked face was hardly ever encountered, thanks to the work done by one of Hunter's pupils, Edward Jenner, on a research farm like the one at Downe, though, of course, not to compare with it in equipment.

This by no means completes the list of Buckston Browne benefactions. One happy notion of his was to endow an annual dinner for the Fellows and Members of the Royal College of Surgeons. For this purpose he set aside a sum of £5,000, the interest from which was to provide a dinner on the College premises for one hundred persons, and he stipulated that one-half of the invited guests should be members of the College (he had been a member himself for over 50 years, the diploma of Fellow being conferred on him by the Council in 1926, in recognition of his services to surgery). Possibly his appreciation of the social value of a dinner arose from his early association with Sir Henry Thompson, whose "Dinners at Eight" (for 8 persons, with 8 courses, at 8 o'clock) were famous Wimpole Street affairs, attended on occasion by royalty.

Sir Buckston Browne also gave £2,000 to University College Hospital, and from his collection presented certain pictures and articles of furniture for the common room of the senior staff of the medical school. His recreation was the study and collection of pictures and objects of art generally. He was the discoverer of previously unknown portraits of John Hunter and John Wesley, and presented them respectively to the Royal College of Surgeons and to Wesley House, Cambridge. He also made presentations of works of art to the Victoria and Albert Museum, the National Portrait Gallery, and the Harveian Society. All that had to do with past times and manners engaged his interest, which was evidenced in various ways. For example, at one of the first of the Royal College of Surgeons dinners each guest received a souvenir in the shape of a model of a catheter found in the surgeon's house at Pompeii, and many other instances of the kind could be cited. He had literary tastes, too, and was extremely proud of the dedication to him by George Meredith of the novel, *Lord Ormont and his Aminta*, published in 1894. In a letter to Mrs. Lister in 1892 Meredith wrote: "I find myself next to rehabilitation by the surgeon. This was Buckston Browne, and no victim of sharp instruments could be in skilfuller or tenderer hands. He did his work perfectly, and I had difficulty in getting him to take his fee."

The Royal College of Surgeons made him a trustee of the Hunterian Collection, presented him with the Gold Medal, and placed his bust in bronze on the staircase at Lincoln's Inn Fields. In 1932 he received his knighthood. His regret was that his wife had not lived to share that honour with him. She had died after a devoted partnership of 52 years. They married in the year in which he entered medicine. In her memory he endowed two cottages for aged people and arranged other benefactions in her native village of Sparsholt in Hampshire, and also dedicated a bed in University College Hospital.

C. FERRIER WALTERS, F.R.C.S.

We regret to record the death on Dec. 24, 1944, of Charles Ferrier Walters, F.R.C.S., consulting surgeon to the Bristol Royal Hospital. The son of Thomas Walters, chartered accountant, he was born on Dec. 26, 1874. He was at school at Burton College, where his uncle, the Rev. Dr. Ferrier, was headmaster. Apprenticed for a short time to a dentist in Park Street, Bristol, he soon decided to become a medical student, and entered the Medical School of University College, Bristol, in 1895. He did his clinical work first at the Bristol Royal Infirmary and later at the London Hospital, qualifying M.R.C.S., L.R.C.P. in 1900. He obtained his F.R.C.S.Eng. in 1904, and in 1909 was elected assistant surgeon to the Bristol Royal Infirmary. In 1915 he was elected full surgeon, and from 1925 until his retirement in 1934 he was senior surgeon to the Infirmary. During the war of 1914–18 Walters rejoined the R.A.M.C.(T.F.) and went to France with a C.C.S. During the Somme battle of 1916 he was given charge of an advanced abdominal operating centre at Aveluy, a new departure in those days, where he did much good work which went far to persuade reluctant authorities that urgent surgery could and should be carried out in the forward areas. This experience coupled with his 25 years of active work at the Royal Infirmary rendered him most eminently suitable for the post of group officer to the Bristol area when the Emergency Medical Service came into being in 1939.

Walters (writes a colleague) was a man of irrepressible energy, always in a hurry to get to work, but in his operating unhurried. He was a sound general surgeon who devoted a good deal of attention to genito-urinary surgery. In his younger days he was a fine gymnast. Throughout his life he loved handiwork—from small carpentering jobs to house-building. These were his relaxations. Among other recreations came sailing and nature study. Yet with all his bodily activity he made time for most varied reading. He was a member of the Moynihan Surgical Club, president of the Bristol Medico-Chirurgical Society (1929–30), and president of the Bath and Bristol Branch, B.M.A. (1932–3). Walters was a loyal, friendly colleague and a good teacher. He married, in September, 1905, Miss Gertrude Popham, daughter of the Rev. J. K. Popham. Their family consists of one son, now serving in the R.A.M.C., and three daughters. We offer our deepest sympathy to his widow, his children and grandchildren.

ISABELLA DOUGLAS CAMERON, M.D.

Members of the public health service and of the dinner club of paediatricians and others whose common bond was an interest in child welfare will learn with regret of the death, in an Edinburgh nursing home on Jan. 10, of Isabella Douglas Cameron, M.D., D.P.H., M.R.C.O.G., who was for 25 years a valuable officer of the Local Government Board and of the Ministry of Health, where she had a large share in the pioneer medical administration work in the setting up of the Maternity and Child Welfare Services, her contributions to which were in some degree rewarded in 1937 by a unanimous invitation of the Council of the Royal College of Obstetricians and Gynaecologists to become a member of their College.

A woman of strong individuality, with imagination and a keen sense of duty, Dr. Cameron received her medical education at the Medical College for Women, Edinburgh, and graduated with distinction in 1898. In 1906 she obtained her M.D. degree for a thesis on "A Study of the Dietary of Several Halls of Residence for Students in Edinburgh"—a companion study to Prof. Noel Paton's work on the dietary of the working classes in Edinburgh. After holding resident appointments at the Crichton Royal Institution, Dumfries, the Children's Hospital, Sheffield, and the Infectious Diseases Hospital, Walthamstow, Dr. Cameron worked in the Cambridge University Laboratories and obtained the D.P.H. of that University in 1905. She then returned to her old school as lecturer in physiology and was also engaged in research work in the Laboratory of the Royal College of Physicians, Edinburgh, where one of the results of her labours was a valuable article on the methods of standardizing suprarenal preparations. One of the processes was subsequently adopted commercially. In May, 1906, Dr. Cameron was appointed medical officer to the Carnegie Dunfermline Trust, a pioneer body so far as Scotland is concerned in the medical examination, treatment, and systematic physical training of school-children. From this appointment she went to that of medical officer to the Edinburgh Provincial Committee for the Training of Teachers, and Dr. Cameron employed the vacations her appointment afforded to visit institutions devoted to the care, management, and treatment of infants and young children in Germany, Canada, and the United States of America.

She was one of the many children of James Cameron of Stanley, Perthshire. One of her brothers is Mr. J. F. Cameron, Master of Gonville and Caius College and lately Vice-Chancellor of Cambridge University. A sister was a distinguished student of mathematics under Prof. Chrystal of Edinburgh.

W. F. MENZIES, M.D., F.R.C.P.

Dr. William Francis Menzies, for 38 years medical superintendent of Cheddleton Hospital, Staffordshire, died suddenly at Radlett on Jan. 12, aged 81. Born at Halifax, Nova Scotia (where his father was then chief cashier in the Bank of Nova Scotia), he came to this country at the age of 12 and entered Fettes College. On leaving school he began the study of medicine at Edinburgh University, graduating M.B., C.M. in 1885 and B.Sc. and M.D. in 1888. He obtained the M.R.C.P.Lond. in 1891 and was elected F.R.C.P. in 1920. Immediately on graduation he took up psychiatric practice, and was a resident M.O. first at the Kent County Mental Hospital, Maidstone, and then for a longer period at Rainhill, near Liverpool. At the end of 1898 he was appointed medical superintendent of the newly established County Hospital at Cheddleton, near Leek. He retired from the post in August, 1936, owing to ill-health.

Dr. Menzies's great skill and knowledge brought him wide recognition. In 1920 he was elected president of the Royal Medico-Psychological Association, and he published a number of valuable papers on mental disorder and deficiency. He was also honorary consulting psychiatrist to the North Staffs Royal Infirmary and honorary neuropsychiatrist to the Stoke-on-Trent Orthopaedic Centre. He joined the B.M.A. in 1891, was secretary of the Section of Neurology and Psychological Medicine at the Annual Meeting at Exeter in 1907, chairman of the North Staffs Division 1932–3, and president of the Staffordshire Branch in 1934–5; he had also been president of the North Staffordshire Medical Society. From the time that Cheddleton Mental Hospital was opened Dr. Menzies collected round him as members of his staff a number of enthusiastic musicians and started an orchestra, which gradually grew until in 1934 members of the staff and friends living in the neighbourhood brought the strength up to nearly 70, the medical superintendent himself conducting it with great success.

SIR THOMAS BARLOW, BT.

R. H. writes:

By the death of Sir Thomas Barlow the father of our profession and its oldest and most honoured member has been taken from us; but "nothing is here for tears, nothing to wail or knock the breast," for he had long outlived the ordinary span of human life. I first got to know him when I had the privilege of serving as his house-physician at the Hospital for Sick Children nearly fifty years ago. He was then at the height of his busy consulting practice, and his ward visits were apt to be hurried, but one quickly came to admire the thoroughness of his clinical investigation, the accuracy of his diagnosis, and, above all, the kindness of his heart. To him the sick were never merely "cases" but suffering human beings requiring his sympathy and help, and to children especially his kindness and sympathy were always most shown. He had also the shrewd common sense of his native Lancashire along with its dry humour. I remember telling him some years ago how, when he was attending Queen Victoria in her last illness and the reporters were waiting at the gate of Osborne House for the latest bulletin, one of them wrote to his paper: "Our spirits rose when we heard that Sir Thomas Barlow had left," and how he chuckled over the joke. But although very much *persona grata* as a physician in the highest circles he was no mere courtier, and he once said, rather wistfully, that he would gladly give it all up and "practise in a dispensary amongst poor folk"; and therein spoke the real man. He had lived so long that latterly he had come to be merely a name to many of the present generation, and it was interesting at an international gathering of paediatrists in London a few years before the war to see the look of astonishment on the faces of many of the foreign visitors—as if they were gazing on one risen from the dead—when he was introduced as the Barlow of "Barlow's disease" and to hear the deafening ovation which followed. Now he is gone, but he has left an inspiring example of a life nobly and usefully spent and of a character entirely upright, simple, and sincere.

Sir ERNEST COWELL writes:

I was privileged to serve as the penultimate house-physician to Sir Thomas Barlow at University College Hospital. This was in the days when the physician made his own diagnosis and confirmed it by laboratory test or *x*-ray examination, which were only just becoming available. The student was taught to draw conclusions by examining the patient all over, noting his tone of voice and texture of the palms and even looking under the bed.

Sir Thomas was the soul of kindness. At the end of a demonstration on a patient, which might take an hour with a pause for hot milk in the middle, he would slip a sovereign in the sister's hand and say, "Poor soul, give her this." In the passing of this great physician the profession has suffered a great loss. It is up to the present and coming generations of doctors to remind themselves of his clinical method, and, as Sir Thomas was always doing, to strive to discover fresh truths.

G. H. writes: I would like to add a few random words to the memoir printed last week, though I only knew Sir Thomas Barlow in the latter part of his long life. We came together about one or two things, more particularly in forwarding the work of the Royal Medical Benevolent Fund, which was a cause he loved more than any other in old age. I also had the happiness of meeting him in the family circle at Wendover among his children and grandchildren, with great-grandchildren in the offing. To have talked with the Nestor of our profession as he sat by the fireside, his hand cupped to his ear because of deafness and his Father Christmas face beaming with benignity, is a memory to treasure. Much has been written and will be written of his great service to medicine. He outlived all his contemporaries and many of his juniors, became a legend, and grew so old that time seemed to have forgotten him. The ceremonial idea of a 100th birthday on Sept. 4, 1945, made us wish that the veteran physician might survive a few more months and add a final decoration to the part he had played in medical history. That was not to be, and who can grudge him his rest? Thomas Barlow's work has fertilized our science and practice; his influence is incalculable, but we may be sure it goes on, passing from generation to generation, and we may doubt if the simple solid humble doctor himself ever imagined that that kind of immortality would be his.

Dr. EDWARD LESLIE HORSBURGH died at his home in Ryde, Isle of Wight, on Jan. 3. He studied medicine in Manchester and graduated M.B., B.S.Lond. in 1910 and M.D. in 1914. He was physician to King Edward VII Hospital for Officers at Osborne and medical referee to the Royal National Hospital for Consumption at Ventnor. During the last war he served as assistant adviser in pathology at the Calais base. Before settling in practice he had been house-surgeon and house-physician at the East London Hospital for Children, Shadwell, and senior house-surgeon at the Manchester Royal Infirmary. In 1929–30 he was chairman of the Isle of Wight Division of the B.M.A. T. T. H. writes: The untimely passing of E. L. Horsburgh will be mourned by many beyond the confines of his native Isle of Wight. Contemporaries in Manchester, London, and the old B.E.F. will recall his sparkling and vivacious personality—his *gaieté de cœur,* irresistible and unforgettable—and his genius for friendliness. It was my privilege to live with him as student, hospital resident, and Army doctor and to know his blithe spirit with a brotherly intimacy. Latterly of necessity our ways diverged, but the occasional reunion found that spirit and our affection undimmed by the passing years. "Whom the gods love die young" may truly be said of Leslie Horsburgh, grey hairs notwithstanding In any company he radiated mirth, hilarity, and good fellowship, for he was a superb raconteur and mimic, and a witty and trenchant conversationalist. Many a "mess" and many a fellow traveller "on life's common way" must remember his camaraderie with gratitude. In truth, his natural endowments were many and various. He could have excelled with ease in other less exacting and more spectacular fields than medicine had he so chosen. Golf, the stage, or letters might all have known him as a star, but he preferred to keep these as hobbies in his life's work as a physician. Who can doubt that he was right?—certainly not the crowded company of those by whom he was beloved as guide, philosopher, and friend. Even in his own profession he eschewed the limelight. His abilities would have carried him to the very front rank in pathology or clinical medicine. Instead he chose general practice. Again who shall criticize his choice? He was assuredly the ideal family physician—skilled, devoted, and always refreshing to the spiritually weary. Humbug he scorned; truth he diligently sought and cherished. Here was a man whom to know was to love and to love was great gain. He "shall grow not old as we that are left grow old."

Dr. ROBERT STEWART of Lytham, Lancashire, died on Jan. 4 He studied medicine at St. Mungo's College, Glasgow, and afterwards in Manchester, taking the diplomas of L.R.C.P.&S.Ed and L.R.F.P.S.Glas. in 1899; eight years later he obtained the D.P.H. of the Victoria Infirmary. Dr. Stewart belonged to the British Medical Association throughout his professional life; he took a keen but unostentatious interest in its work and was a diligent reader of the *Journal*. He attended and enjoyed many of the Annual Meetings, and was a member of the World Tour in the summer of 1935 when the B.M.A. met in Melbourne.

Dr. **Edward Smallwood**, of Knight's Hill, West Norwood, S.E., died on Jan. 15 at King's College Hospital. He studied medicine at University College, Liverpool, and in London, took the L.S.A. in 1894 and the M.R.C.S., L.R.C.P. in 1901, and soon afterwards obtained the M.D.Brussels degree. He held various junior posts at the Royal Infirmary, Liverpool, before settling in practice at Norwood, where he became medical officer to the Home for the Aged Poor and visiting medical officer to the local children's hospital. During the last war he served as honorary physician to the Chelsea War Hospital, the Meynell Hospital for Officers, and the Lambeth Auxiliary War Hospital. Dr. Smallwood joined the B.M.A. in 1889 and was a past president of the Norwood Medical Society.

A great personality has gone with the death of Dr. **Jane Lorimer Hawthorne**. She was one of the pioneers of sex education for the young and attempted successfully to tear down the veil of prurient mystery with which it had been enveloped. As a lecturer for the Alliance of Honour and the British Social Hygiene Council she had great success. A sense of humour helped her in this, as also did her power of ranging herself along with her audience. She was not a lecturer "telling people" but one of themselves discussing the matter. She positively welcomed interruptions, and would follow them down any by-way that her audience wanted. As medical officer to child welfare centres in the early days she was able to give information in a form acceptable to the working-class mother. Her views (as in all matters) were very definite, and those on the subject of dummies for babies overflowed on to the walls of her Canning Town clinic. It was not enough for her that a normal healthy child had been produced and that the mother had satisfactorily established breast-feeding; there was always a careful examination with a note on the involution or position of the uterus and the condition of cervix and perineum. New ideas were always being tried out: there was no fear of mental stagnation when Dr. Hawthorne was about. Ill-health had diminished her activities for some time, and a love of gardens and plants was added to her other interests. One could not be in her company without realizing a very remarkable, original, and many-sided personality.—L. M. P.

Dr. **Ernest Worley**'s death, while a great loss to the B.M.A. as a whole, will be particularly felt at the meetings of the City Division. Every year (writes a colleague) he drew up a programme of monthly scientific meetings where the lectures were much appreciated and followed by good discussions. He was able to infuse informality and friendliness so that the youngest, shyest, and most retiring members were made to feel that their opinions were wanted. Those who had held office will long remember the dinners before the scientific meetings, where they had an opportunity of making personal contact with the lecturer. All this meant a good deal of organizing work, which was never shirked when medical work was heavy or when Dr. Worley might have been thought to be fully occupied as organizing secretary for the Centenary Meeting. Dr. and Mrs. Worley loved the Division, and the Division loved them.

C. J. de V. S. writes: To everyone who knew **J. J. O'Mullane**, whether as friends or patients, his early death will cause much sorrow and leave behind a void it will be hard to fill. His great understanding and sympathy for those in trouble, his readiness to give a helping hand to whomsoever needed it, endeared him to all who came in contact with him. He had an outstanding sense of humour—a ready Irish wit which would often waft away the cares and troubles of his patients. For many years he suffered from indifferent health, but his insuperable energy and his indomitable courage made him carry on his practice, never sparing himself day or night to go to the aid of those who needed him. Although his practice was large he never failed to keep in touch with the latest advances in medicine, and his treatment was always the most modern. His knowledge of medicine was extensive, and if he had not felt his work lay in general practice he would have attained great heights. I have worked with him, and no words can speak too highly of him as a colleague. His early death at the age of 52 years has cut short the work he was doing in Plumstead—work in which his heart lay; but in the minds of all who knew him one thought remains above all: "He was a man."

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The programme of lectures on science in the history of thought, to be delivered in Mill Lane Lecture Rooms at 12 noon, includes one on Saturday, Feb. 10, by Dr. A. E. Clark-Kennedy on medicine and the progress of thought. These lectures are open, without fee, to all members of Cambridge or London University or of Girton or Newnham College.

UNIVERSITY OF LONDON

L. S. Penrose, M.D., has been appointed to the Galton Chair of Eugenics tenable at University College. He has been attached since 1939 to the Provincial Department of Health, Ontario, Canada, and is also a physician at the Ontario Hospital, lecturer in psychiatry in the University of Western Ontario, and medical statistician for the Province.

C. Rimington, Ph.D., B.Sc., has been appointed as from May 1 to the University Chair of Chemical Pathology tenable at University College Hospital Medical School. Since 1937 he has been on the staff of the National Institute for Medical Research.

The following candidates have been approved at the examinations indicated:

M.D.—BRANCH I *(Medicine)*: James Marshall. BRANCH II *(Pathology)*: R. E. O. Williams. BRANCH IV *(Midwifery and Diseases of Women)*: G. C. Brentnall, E. Garland Collins. BRANCH V. *(Hygiene)*: Sarah C. B. Walker.

UNIVERSITY OF GLASGOW

A graduation ceremony was held on Jan. 13, when the following medical degrees were conferred:

M.D.—*Thomas Anderson, †H. W. Bowyer, †T. McM. Curran, R. D. Campbell.

M.B., CH.B.—A. R. Beaton, J. E Bennett, Katharine N. Brittain, D. F. Bruce, J. P. G. P. Burnie, A. C. Connell, M. S. Crawford, W. A. Crawford, J. L. Crichton, W. Cullen, W. J. A. Dobson, Agnes P. Downie, R. E. Evans, R. C. Forrest, J. Freedman, Arthur Jamieson, J. L. Kelly, L. Kennedy, W. I. Kenyon, G. J. Ker, R. Lindsay, R. McP. Livingston, Margaret J. MacArthur, J. B. Macmillan, T. P. Magee, S. S. Meighan, W. Napier, A. J. Nelson, J. A. Porter, G. B. Prentice, Jean A. Purdie, J. T. W. Robertson, S. J. T. Robertson, Janette C. Russell, T. Smart, J. R. Smith, Raymond Smith, Rose K. Smith, Isobel D. Stewart, J. B. Stirling, F. H. Stone, K. J. Whitelaw, T. C. D. Whiteside, A. M. Williamson, Alexander Young.

* With honours. † With commendation.

The Brunton Memorial Prize was awarded to J. K. Watt as the most distinguished graduate in medicine of the academic year 1943–4, and the West of Scotland R.A.M.C. Memorial Prize to C. M. Ross as the candidate with the highest aggregate number of marks in surgery, medicine, and midwifery in the final examinations for the degrees of M.B., Ch.B., 1943–4.

UNIVERSITY OF WALES

THE WELSH NATIONAL SCHOOL OF MEDICINE

The following candidates have satisfied the examiners at the examination indicated:

M.B., B.CH.—*(Hygiene)*: D. Anthony, J. H. Edworthy, Hannah P. Evans, J. C. Ham, I. D. Jacobs, Jane W. James, D. G. Jones, D. O. Lewis, D. R. Lewis, W. T. Lloyd, Olwen V. Rees.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A quarterly meeting of the Council of the College was held on Jan. 11, under the chairmanship of the President, Sir Alfred Webb-Johnson, who was warmly congratulated by the Council on the award of a baronetcy. Arrangements were made for the delivery of professorial lectures on anatomy by Prof. A. J. E. Cave and on physiology by Prof. John Beattie. The first course will begin on Feb. 19. It was reported that the trustees of the Prophit Trust had reappointed Dr. D. E. Lea of the Strangeways Laboratory, Cambridge, and had appointed Mr. Peter C. Williams of the Middlesex Hospital, Prophit Research Students.

It was decided to recognize the posts of first and second house-surgeon of the Royal Northern Infirmary, Inverness, for the six months' surgical practice required of candidates for the Final Fellowship examination.

Diplomas

Diplomas of Membership were granted to Flavia Z. L. B. James and H. B. Marsden.

Diplomas in Public Health, in Psychological Medicine, and in Laryngology and Otology were granted jointly with the Royal College of Physicians of London to the following candidates:

DIPLOMA IN PUBLIC HEALTH.—P. S. Jaikaran, H. G. Williams.

DIPLOMA IN PSYCHOLOGICAL MEDICINE.—P. Cassar, Louise F. W. Eickhoff, R. K. Freudenberg, G. W. Green, D. Jackson, P. D. Scott, L. M. Sborvon, G. D. F. Steele, E. Wellisch.

DIPLOMA IN LARYNGOLOGY AND OTOLOGY.—R. G. Boyd, A. S. Davidson, N. A. Punt, G. Snowden, P. A. Thorpe.

ROYAL COLLEGE OF SURGEONS IN IRELAND

Prof. W. N. Rae, Sc.D., Registrar of the Royal College of Surgeons in Ireland, Dublin, has received the following letter from Sir Alfred Webb-Johnson, President of the Royal College of Surgeons of England, dated Dec. 28, 1944:

> "I beg to acknowledge with thanks the receipt of your letter of the 22nd instant enclosing a donation of one hundred guineas from the Royal College of Surgeons in Ireland to the fund for the restoration of my College. I shall be glad if you will inform the President, Vice-president, and Council of your College that this spontaneous gesture is very deeply appreciated by me and my colleagues on the Council of this College. The gift will always be remembered as a token of our friendly relationships and as an earnest of our cordial co-operation in the future."

Medical Notes in Parliament

Women Medical Students: Admission a Condition of Grant

Dr. SUMMERSKILL on Jan. 18 asked Mr. Willink to make a statement on the report of the Interdepartmental Committee on Medical Schools.

Mr. WILLINK replied that the committee recommended a comprehensive programme for the reform and development of medical education and research. Certain of the matters involved would require legislation. These the Government proposed to discuss with the bodies concerned. Apart from these the committee's recommendations were in the first place for the responsible educational authorities to study in framing their future policy. The Government accordingly invited universities, medical schools, and teaching hospitals to give the report early consideration. Recognizing the fundamental importance of medical education and research to the future of the country's health services, the Government accepted the principle of increased grants for the purposes of medical education and research to be distributed by the University Grants Committee through the universities to medical schools, postgraduate schools and institutes, and hospitals used for teaching and research. They also accepted the suggestion that for a limited period these additional grants should be separated from the block grants received by universities for their work as a whole. The amounts of grant to be made from time to time, whether for capital or for recurrent expenditure, would be determined after consideration in the light of the recommendations of the University Grants Committee and the general financial position prevailing. The Government shared the views expressed in the report on the importance of affording to women equal opportunities to those enjoyed by men for medical training and for obtaining postgraduate experience. They had therefore decided, as recommended by the committee, that future payments of grant to medical schools should be conditional on the adoption by the school of the principle of admitting a reasonable proportion of students of both sexes. They recognized that schools at present open to one sex only might need periods of varying lengths to adjust their arrangements to a co-educational basis. They therefore proposed that the University Grants Committee in consultation with the university authorities concerned should be charged with the responsibility of determining from time to time whether the action taken by each of these schools complied with the principle to the extent that is reasonable. The Government attached equal importance to the revision of the medical curriculum. Their acceptance of the principle of increased grants for medical education and research was dependent on the early completion of this process. They were glad to learn that, as recommended by the committee, the General Medical Council had already taken the initiative in the matter.

Deaf Aids Committee

Sir D. HACKING asked on Jan. 8 for the names of the members of the committee appointed to advise and assist the Medical Research Council in promoting research into electro-acoustical problems of design and application of instruments in alleviation of deafness.

Mr. ATTLEE: The members of the committee are as follows: Dr. W. G. Radley (chairman), Mr. E. J. Barnes, Sir Lawrence Bragg, Mr. N. Fleming, Dr. C. S. Hallpike, Mr. L. C. Pocock, and Dr. T. S. Littler (secretary). The committee has formulated a detailed programme of research, and investigations in which physicists are collaborating with otologists and physiologists are in progress. The investigations will take some time to complete, and it is not anticipated that the committee will be in a position to make any recommendations before the end of the year.

Tuberculosis in Repatriated Prisoners of War

On Jan. 16 Miss WARD asked the Secretary of State for War whether he was aware of the dissatisfaction of relatives with the arrangements made for repatriated prisoners of war suffering from tuberculosis; and if he would consider these complaints with a view to an alteration of the present policy. Sir JAMES GRIGG replied: It is the policy of the Army to discharge soldiers suffering from tuberculosis as soon as possible so that if necessary they may enter civil sanatoria near their homes. Repatriated prisoners of war are given special consideration, but I am aware that there is sometimes delay in admission owing to pressure on accommodation. The Minister of Health has therefore set aside a number of beds in E.M.S. hospitals specially for Service patients awaiting transfer to sanatoria. This should materially help to remove any cause for complaint.

Miss WARD asked if Sir James Grigg would inform the Minister of Health that his arrangements were most unsatisfactory and ask him to improve them in the future. Sir JAMES GRIGG said he would certainly pass on the message, but whether he should do it in quite those truculent terms was a matter he would like to consider. Dr. SUMMERSKILL: In view of the fact that these men contracted the disease in the Army, can Sir James Grigg say why he is shelving his responsibility in this matter? Sir JAMES GRIGG: Because that happens to be the arrangement prescribed in the Army Regulations. The Army does not look after tuberculous patients. Patients discharged for disability in the Army are looked after, in the case of tuberculosis, by the Ministry of Health, and in the case of other diseases in Ministry of Pensions hospitals.

Distillation of Salt Water

On Jan. 16 Capt. STRICKLAND asked the Parliamentary Secretary to the Ministry of War Transport what steps had been taken by the Government to encourage research into the conversion of salt water into drinking-water by demineralization, evaporation, or other processes; whether any effective and convenient method had been evolved; and whether it was proposed to make the fitting of the necessary apparatus compulsory on all sea-going vessels, including their boats. Mr. NOEL BAKER said that the Government had done extensive research into the distillation of salt water by demineralization and evaporation, and apparatus designed by private inventors had been examined and tested. As a result two types of fresh-water producers for lifeboats were now issued on free loan to shipowners. A third and smaller pattern for use in emergency rafts was in production. Sea-going vessels carried adequate supplies of drinking-water for use on board. The filtering type as well as the distillation type was being used.

Medical News

A meeting of the Medical Society for the Study of Venereal Diseases will be held at 11, Chandos Street, W., to-day (Saturday, Jan. 27) at 2.30 p.m., when Dr. David Erskine will give an address on "Difficulties in the Successful Treatment of the Venereal Disease Patient."

Dr. Andrew Topping will speak on the "Aims of U.N.R.R.A. in the Health Field" at a meeting arranged by the Polish Medical Association in the U.K. to be held in the Hastings Hall of B.M.A. House, Tavistock Square, on Jan. 30, at 5 p.m. The lecture is open to all and will be followed by questions and discussion.

Prof. T. Wallace, D.Sc., will deliver two lectures on "The Diagnosis of Mineral Deficiencies in Crop Plants" before the Royal Institution, 21, Albemarle Street, W., on Tuesdays, Jan. 30 and Feb. 6, at 5.15 p.m.

The Science (Research) Society has arranged two public lectures. The first, on Wednesday, Jan. 31, at 6.45 p.m. in the City Literary Institute, Stukeley Street, Drury Lane, W.C., will be by Lady Eve Balfour, of the Haughley Research Trust, on "The Living Soil"; the second, on Saturday, Feb. 24, at 3 p.m. in the Hastings Hall of B.M.A. House, Tavistock Square, will be a technical discussion on "Soil Biology," by Lady Eve Balfour and Dr. E. W. Russell of the Rothamsted Experimental Station.

The Seventh Addendum to the *British Pharmacopoeia, 1932*, which was noticed in an annotation last week (p. 89) will be published on Feb. 1, and becomes official from that date. Constable and Co. Ltd., 10, Orange Street, Leicester Square, London, W.C.2, publish it for the General Medical Council.

Prof. F. Wood Jones, F.R.S., F.R.C.S., will give an address on "The Mammalian Toilet" before the Royal Institution, 21, Albemarle Street, W., on Friday, Feb. 16, at 5 p.m.

The following lectures will be delivered at the Royal Institute of Public Health and Hygiene, 26, Portland Place, W., on Wednesdays, at 3.30 p.m.: Feb. 7, Surg. Rear-Adml. G. Gordon-Taylor, "Surgery and Russia"; Feb. 14, Dr. G. H. Newns, "The Problem of Infant Mortality"; Feb. 21, Dr. I. H. MacLean, "The Problem of Whooping-cough Immunization"; Feb. 28, Dr. Harold Balme, "The Place of Rehabilitation in Hospital Service"; March 7, Lord Forrester, "Industry and its Environment—Physical and Social"; March 14, Mr. V. Zachary Cope, "Surgery in the Life of To-day"; March 21, Dr. Janet Aitken, "Rheumatism in Children"; March 28, Mr. Frederick W. Pratt, "Some Obstructive Abdominal Conditions in Infancy."

Field-Marshal Alexander has convened a medical conference, to be held in Rome at the end of the month, which will be attended by leading medical officers from the Allied Medical Services.

Orange-juice jelly, having a declared minimum content of vitamin C of 12 mg. per oz., will be available to school canteens, residential schools, etc., from Feb. 4, price 6½d. a lb. in cases of 42 lb. The average potency of the vitamin is expected to be about 17 mg. per oz. Local food offices will issue particulars of the scheme to the establishments concerned.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week the incidence of measles rose steeply, 3,077 more cases being notified than in the previous week. Acute pneumonia, whooping-cough, and dysentery also showed increases, of 430, 359, and 81 respectively. There were 50 fewer cases of scarlet fever.

The rise in whooping-cough was general throughout the country and there were no large local variations in incidence. Yorks West Riding reported a fall of 52 in scarlet fever notifications. Those of pneumonia were the highest for a year, and in Lancashire, Warwickshire, and Yorks West Riding there were increases over last week's totals of 98, 51, and 50 respectively. Practically every county showed a substantial increase in measles: Warwickshire reported 415 more cases than last week, Lancashire 323, Staffordshire 321, Nottinghamshire 306, Cheshire 209, Yorks West Riding 193, Durham 131, and Middlesex 117.

Returns for dysentery in London rose from 16 to 67 (Wandsworth 44). The other large returns were those of Lancashire 24, Surrey 21, Yorks West Riding 13, Essex 11.

In *Scotland* measles notifications were 226 higher than last week, and whooping-cough 31, while the only disease to decline in incidence was scarlet fever, with 26 fewer cases than last week. The notifications of cerebrospinal fever, 37, were the highest in recent months; one-half of these cases were recorded in Glasgow. The largest returns of dysentery were Glasgow 37, Edinburgh 13, Lanark County 13, and Fife County 10.

In *Eire* a fall in the incidence of diphtheria reduced the notifications by 81, but the disease is still widespread: the 110 cases were reported from fifty areas.

In *Northern Ireland* infectious diseases were more prevalent. The increases over last week's totals were: Measles 93, scarlet fever 18, diphtheria 12, whooping-cough 8. In Belfast C.B. notifications of measles and whooping-cough rose by 100 and 8 respectively. Londonderry had 8 more cases of diphtheria than last week.

Quarterly Returns for England and Wales

During the September quarter the birth rate was 17.6 per 1,000 and was the highest rate for a third quarter since 1926. The birth rate in the third quarter of 1943 was 16.2, and the average for the third quarters of the preceding five years was 15.0. Infant mortality was 40 per 1,000 live births—below the average of the ten preceding third quarters. The diarrhoea death rate under 2 years of age was 6.4 per 1,000 live births, compared with 5.9, 5.2, 5.1, and 3.5 in the preceding four quarters. The stillbirths represented 2.7% of the total births registered. The general death rate was 10.3 per 1,000, compared with 9.4 for the third quarter of 1943, and with 9.9 for the average of the five preceding September quarters. The natural increase, excess of births over deaths, was 76,340, the corresponding figures for the third quarters of 1941–3 being 46,285, 71,000, and 70,833 respectively. There were 164,604 persons married in the quarter—an increase of 1,696 on the third quarter of 1943, but 76,408 below the five-years average.

Week Ending January 13

The returns of infectious diseases in England and Wales during the week included: scarlet fever 1,330, whooping-cough 1,678, diphtheria 459, measles 10,979, acute pneumonia 1,399, cerebrospinal fever 53, dysentery 302, paratyphoid 5, typhoid 5. Seventy-two deaths were attributed to influenza in the 126 great towns.

No. 1

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 6.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London) (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

ANY QUESTIONS?

Inheritance of Cancer

Q.—*What are the latest views on the inheritance of cancerous tendencies? Is there evidence to support the popular view that such tendencies are hereditary or familial?*

A.—Though actual proof is not an easy matter, there can be little doubt that heredity does play some part in the determination of neoplasms in the human subject. Such tumours as glioma of the retina, the neurofibromas of von Recklinghausen's disease, and polyps of the large intestine are hereditary beyond any doubt. But how large is the hereditary factor? This cannot easily be answered by statistical investigations on man; the generations pass too slowly, and errors of various kinds creep in. Cancer families have been described, and a mere statement of the observed facts is impressive. For example, in a family studied by Warthin there were 175 individuals in four generations of whom 41 died of cancer; 26 cases were of the gastro-intestinal tract and 15 of the body of the uterus. But in a disease so widespread as cancer the chance accumulation of cancer in one family may occur. We must therefore depend upon deliberate experiment in short-lived animals—e.g., the mouse—in which irrelevant elements can be bred out by brother-sister matings and the tendency or lack of tendency to cancer can be concentrated. Genetic investigations of this sort have proved conclusively that for certain cancers—especially mammary, lung, and bone tumours—heredity is an important factor in the genesis of cancer. In mammary cancer it has been proved conclusively that the inherited tendency to cancer, transmitted by male or female and therefore chromosomal in origin, added to the action of the hormone oestrone and a factor present in mother's milk of high cancer strains, are, all acting together, essential to the development of tumours of the breast.

Epileptic Fits in Theatre

Q.—*A patient aged 17 has had epileptic fits for two years. They occur only when he visits a theatre or cinema, and take the form of convulsions, biting of the tongue, incontinence of urine, followed by headaches, giddiness, and falling to sleep. He vomits after the fit. Recently he has bed-wetted. Physical examination reveals nothing abnormal. Although the fits seem to be those of idiopathic epilepsy, are they possibly functional, as they occur only in the circumstances described?*

A.—These are undoubtedly epileptic attacks. There is no suggestion that they are hysterical. In some patients epileptic fits arise in response to highly specific stimuli and in highly specific circumstances. It is usual to find that, although a special trigger will produce a fit, they also occur spontaneously, and it is likely that the recent bed-wetting is the result of unrecognized nocturnal attacks. The present story is interesting, though not remarkable, and at least the patient knows how to reduce the number of his attacks.

Recurrent Phlebitis

Q.—*A man aged 53, weight 14 st., is subject to frequent attacks of phlebitis chiefly affecting superficial veins. Eight years ago he had a large infarct in the lung. He is strong and healthy and does not appear to have any other disease. Can you offer suggestions about treatment?*

A.—To cause a recurrent phlebitis there must be a septic focus somewhere which "spills over" into the blood stream from time to time. The common foci are the nasal sinuses, the tonsils (especially if there has ever been a quinsy), and the teeth—either carious or dead, or dead and filled. As the man weighs 14 st. he may have gall-stones (a previous history of typhoid is occasionally present). The prostate may be the focus, and the urine should be examined for pus cells after a prostatic massage. The patient may be a diabetic with declared glycosuria; or hidden diabetes with no glycosuria but a high blood sugar may be found. The fact that the phlebitis is in the leg indicates diseased veins here, almost certainly varicose. The remedy, therefore, is to locate and eliminate the septic focus and to have the varicose veins treated by a surgeon expert in this.

Excessive Flatus

Q.—*A male aged 65 suffers from excessive flatus—so bad that he has to leave the room several times a day to expel it. Bowels act regularly with paraffin. At times the colon becomes so disturbed as to resemble megacolon under x-ray examination, which also reveals much spasm of the colon. There is considerable pain in the left loin—probably the result of the gaseous distension. Belladonna gives no relief. What treatment would you advise?*

A.—In later life absorption of gas from the bowel may be diminished owing to age changes in the blood vessels. Efforts should therefore be made to check the formation of gas from air-swallowing or fermentation in the colon. Excessive flatus is characteristic of intestinal carbohydrate dyspepsia, in which incompletely digested starch grains reach the colon and give rise to acid and gas there. Most authors attribute this to a disturbance of intestinal motility, and phenobarbitone, gr. 1/2 to 1 b.d., may be of value in checking hypermotility and spasm. A mucilaginous aperient such as psyllium seeds or one of the proprietary preparations thereof would probably be better than liquid paraffin. Potatoes and rice should be forbidden and takadiastase gr. 5 given at meal-times.

Control of Colostomy Evacuations

Q.—*A patient who had a permanent colostomy performed in May, 1944, has never been able to control the colostomy evacuations, which do not occur with reference to meals. I have tried allowing him one big meal a day, at midday, and thereafter fluids only. He has been given bismuth in a mixture, as well as tinct. opii, but to no avail. What do you advise?*

A.—The question does not provide enough information to enable a useful reply to be given. What was the type of colostomy:—was it transverse or sigmoid colon which was used? What was the condition for which it was performed? Are the motions loose or merely erratic in their appearance? Answers to all these questions are necessary before an opinion can be given. A transverse colostomy is usually rather more difficult to control than a left iliac, owing to the difference in the consistency of the contents of these regions of the colon. Then, again, the original condition may be present proximal to the opening as well as distal—for instance, a secondary carcinoma or a widespread diverticulosis, and so on. Most colostomy patients find the secret of success lies in the establishment of a moderate degree of constipation; but while some rely upon this alone, others adopt a regular routine wash-out of the bowel twice a day. Either of these methods may be entirely satisfactory, and it is not possible to prognose which will be the better for any individual patient. Both should be given a trial. Of course, considerable modifications of the diet are often necessary to achieve the desired consistency of the motions, and because of the great idiosyncrasies of the bowel the patients usually find out for themselves what article of diet they must forgo.

Malaria and Pregnancy

Q.—*An English lady of 32 had malaria 12 months ago on the Gold Coast. She returned to England last July, and was free from attacks until the beginning of December, when she had two with two days' interval. She is expecting her second baby in February. How much quinine can safely be given to stop the attacks? Is mepacrine less dangerous? Is the baby likely to be infected with malaria? Her first baby was born 2 years ago on the Gold Coast, and she took 4 gr. quinine daily as a prophylactic during the whole time of her pregnancy without any ill effect.*

A.—Thirty grains of quinine daily may be given to stop the attacks of malaria if they occur, but in view of the possibility, so near term, of quinine's having some action on the uterus, mepacrine 0.2 g. thrice daily for 2 days, and then 0.1 g. t.d.s. for 5 days, would be preferable for this purpose. It would be infinitely better, however, to forestall relapse of the malaria by giving a suppressive course of mepacrine forthwith and continuing it for at least one month after parturition. One tablet (0.1 g.) daily should be taken throughout the period to achieve this end. The risk of the infant's being infected is negligible.

Fungus Infection of Toes

Q.—*A boy of 15 had a reddish rash with very small papules on the dorsum of his large toe, causing no pain or discomfort. This improved in the holidays with soaking in weak permanganate of potash. The condition has now spread to several other toes on the same foot. Is this a fungus infection, and what is the treatment?*

A.—A diagnosis may be made on inspection, or by the correct method of direct microscopical examination and culture with the object of proving the presence of ringworm fungus and the kind of fungus causing the infection. The second procedure is recommended, as otherwise the diagnosis rests upon guesswork.

Chemotherapy for Spastic Colitis

Q.—*Having moderately severe spastic colitis, considered to be the late aftermath of an acute enteritis contracted some years ago, I was put on a 5-day course of a total of 30 g. of sulphaguanidine with marked benefit, followed by partial relapse a month later. I repeated the course with further benefit and lesser relapse. I should like to know the views on the toxicity of sulphaguanidine. What precautions apart from blood count are advised, and how frequently can such courses be repeated?*

A.—Sulphaguanidine owes its action in the lower bowel to the fact that a large proportion of it is not absorbed at all; hence the blood levels attained are low, and, as would be expected, toxic effects are rare. The risk even of frequent repetition of the short course specified is very slight, and no special precautions are necessary except the cessation of treatment in the unlikely event of toxic symptoms being produced, such as fever or urticaria. The necessity for further repetition argues some degree of failure, and might be considered an indication for substituting succinyl sulphathiazole (sulphasuxidine); the degree of absorption of this drug is even less, and its antibacterial action in the bowel is somewhat more potent.

"Stress Incontinence"

Q.—*A young girl, aged 23, who suffers from the distressing condition of urinary incontinence only in increased abdominal pressure, especially when laughing, is engaged to be married but dreads the day because of this complaint. There is nothing in the urine beyond phosphates. She is healthy. She has been tried with sedatives, ephedrine, and ergot, but to no avail. Is there anything in the fact that the uterine muscle is of the same structure as the sphincter? I should be glad of advice on the subject. If the line of treatment is ergot, how long should the treatment be kept up?*

A.—Stress incontinence, believed to be due to a developmental weakness of the sphincter mechanism of the urethra and bladder neck, does occur in nulliparous women but does not usually manifest itself until later in life, when muscle atrophy sets in. It is rare in young girls, and in this case other causes should be excluded by careful investigation. Early organic nervous disease affecting the spinal cord, spina bifida occulta, a small pelvic tumour, lesions within the bladder or urethra—including developmental faults such as diverticulae, and a minor degree of epispadias which might not be noticed on inspection of the external meatus—are among the possibilities. Masturbation is also said to cause stress incontinence in young women. Apart from a thorough examination of the nervous system, examination under anaesthesia and cystoscopy may well be indicated.

If, after exacting inquiry, no other cause can be found, then a congenital or developmental weakness in the muscles and fasciae concerned in the control of the urethra must be assumed, and treatment is not easy. For stress incontinence due to obstetrical injury, various plastic operations on the bladder neck and urethra are carried out, but the results are by no means uniformly successful. In a case such as this, if the musculature is inherently weak then such operations would be even less likely to be successful, and something in the way of a fascial transplant from the abdominal wall to form a sling round the urethra might be required. It is difficult to say whether operative treatment is indicated here; it depends how troublesome the incontinence is, how often it occurs, what part is played by anxiety and loss of confidence, whether the patient intends to have children—and if so it might be more opportune to deal with it when the incontinence has been made worse—as it is likely to be—by childbearing. Unless the loss of bladder control is frequent and really troublesome, treatment on more general lines seems preferable, at any rate for the moment.

The patient should be told to pass urine frequently and to avoid a full or distended bladder. Contrast baths might help to tone up pelvic musculature, but, above all, pelvic-floor exercises should be tried. The urethral sphincters are assisted by the "accessory sphincter muscles"—i.e., the levatores ani and other muscles of the pelvic floor—and these might be trained to compensate for the weakness of the involuntary structures. Calcium and nux vomica are advised, but drugs are not likely to improve matters. Ergot in the form of the liquid extract was advised by some of the older writers. If it has any action on the involuntary sphincters, then presumably it is by reason of its alkaloids, ergotoxine or ergotamine, which have a stimulating effect on plain muscle supplied by motor sympathetic nerves. But recent workers suggest that the involuntary sphincters of the urethra are controlled by parasympathetic rather than sympathetic nerves, and in any case it is difficult to see how contractions resulting from ergot could have any lasting effect on the incontinence. Moreover, since ergotoxine and ergotamine are both liable to produce gangrene, they could not safely be given for more than a few days at a time.

It is not clear what is meant by the statement that the uterus and the urethral sphincter are of the "same structure." There is not a single sphincter in the female, but rather a sphincter mechanism which is complex and by no means fully understood. The internal and external sphincters are composed of involuntary muscle, the latter being of little significance. Between the two is the compressor urethrae, which is at least partly under voluntary control. To these must be added the fibromuscular fascia and ligaments lying beneath the anterior vaginal wall and around the urethra and bladder neck, and the accessory sphincter muscles of the pelvic floor; the length and direction of the urethra and the position of the bladder in the pelvis also play a part. It is not possible to compare a system of this kind with the uterus, and the only comment which might be made is that if this patient's incontinence is due to developmental weakness of the musculature of the urethra and surrounding parts, then the supports of the uterus and vagina may be similarly affected and she is perhaps predisposed to prolapse.

Treatment of Undulant Fever

Q.—*One of my patients, a man aged 53, has had undulant fever for 4 months. After 6 weeks the agglutination reaction of Brucella abortus was positive to a titre of 1:1250. His temperature still varies from 99° to 101° F. I understand that T.A.B. vaccine given intravenously is sometimes useful in cutting short the pyrexia. I shall be grateful for any information regarding this, or any other form of treatment, with details of dosage, etc.*

A.—Protein shock with T.A.B. vaccine has been used with some measure of success in undulant fever. It is usual to give three intravenous injections containing 25, 50, and 100 million organisms at 4 to 5 day intervals, but dosage will depend on the degree of pyrexial reaction to the first injection. A course of sulphonamide is sometimes effective, but it should not be continued beyond 10 days without white-cell counts. Another drug that has been recommended for undulant fever is "fouadin" (stibophenum) injected intramuscularly: the dosage is 1.5 c.cm. on the first day, 3.5 c.cm. on the second day, and then 5 c.cm. on alternate days. However, this patient's illness has already lasted 4 months and is likely to terminate spontaneously at any time now (the average duration of abortus fever is 10 weeks), so that it is doubtful if any heroic measures should be instituted at this stage.

A Case of Eunuchoidism

Q.—*A well-developed and otherwise healthy boy of 17¾ was brought to me because his voice had not "broken." He had no sign of hair on the face. Pubic hair was, with the exception of two or three downy hairs, also absent. Penis was diminutive, and scrotum atrophic and empty. No sign of presence of testes anywhere was obtained. A course of gonadotrophic hormones was begun at once without result. What further treatment is indicated?*

A.—The failure to respond to gonadotrophic hormones suggests that the primary disorder is gonadal and not pituitary, the diagnosis therefore being eunuchoidism. It seems improbable that one could produce gonadal development in this case; but secondary sexual characteristics would be developed, or maintained, by androgens. These could be given in three forms: (1) injections of testosterone propionate, 25 mg. twice weekly for 6 or more weeks; (2) methyl testosterone, 5-mg. tablets dissolved under the tongue, 1 t.d.s., for similar periods; (3) the implantation of 6 testosterone propionate pellets, 100 mg. each pellet, in the subcutaneous fat of the abdominal region, the effect lasting some 8 months. On cessation of therapy, in all methods, there is a tendency to regression, but not complete. Nevertheless, the therapy is substitution therapy, and has to be carried out continuously or intermittently if remission is to be avoided.

As to the question of the undescended testicles, even if the condition is primarily of pituitary origin, descent will not be obtained by the administration of hormones should the testes be ectopic and mechanical anatomical obstruction be present. Occasionally cases have been described, of similar character to the present one, in which the gonads unexpectedly turned out to be ovaries or ovo-testes.

Sleep-walking

Q.—*A girl aged 14, normal in every respect, recently walked in her sleep. She dreamt she was going for a walk through a window. She climbed out of the window of her bedroom, and dropped 20 ft. on to the stones below, fracturing her spine. She is known to have walked in her sleep only once before. She is a stable girl, with apparently strong nerves, and not upset by such things as bombing, etc. What precautions could be taken against a repetition of the above?*

A.—Sleep-walking (like dreams) is a sign of an unresolved problem: in psychological language it is a case of "perseveration"—i.e., the tendency of the mind to revert to an unfinished train of thought. In ordinary language we call it "worry"; but in sleep-walking the worry has been repressed and has become dissociated and therefore acts automatically. Usually in a dream the attempt to work out the problem takes place purely subjectively, and without discharging itself in any motor path. But occasionally the problem is so urgent and vivid that, as in the case of Lady Macbeth, it discharges itself in action, and this action takes the form of re-enacting the original unresolved problem to try to find a solution. The dream helps us to discover what that problem is. Obviously the only satisfactory way of preventing a recurrence in this girl is to find out what that problem was, or is, and for this a really good medical child-psychologist should be consulted. It is quite usual for those having subjective problems and anxiety to be free from objective fear, as of bombs, and also to appear perfectly normal in behaviour.

Vitamin C and Hay-fever

Q.—*I have seen it stated that hay-fever has been cured or greatly alleviated by large doses of vitamin C—up to 500 mg. a day. The authority quoted is Dr. Holmes, president of the American Chemical Society, 1942. Has this investigation been followed up, and where is further information obtainable?*

A.—It was claimed by Holmes (*Southern Med. Surg.*, 1943, **105**, 56) and Holmes and Alexander (*Science*, 1942, **96**, 497) that vitamin C in doses of 200 to 500 mg. daily is effective in the treatment of hay-fever. The clinical trials, however, were not adequately controlled, and in Holmes's series conclusions were based on the study of only 25 patients. Strict control is essential in all studies on allergy. Other workers have failed to substantiate the claims made for vitamin C in the treatment of hay-fever (*J. Amer. med. Ass.*, 1939, **112**, 662; *J. Allergy*, 1944, **15**, 236).

LETTERS, NOTES, ETC.

"Skiagram"

Dr. H. CLEMENT SIMCHOWITZ (Guildford) writes: With reference to this matter may I be allowed to correct the quotation of Roentgen's paper in the letter from your correspondent (Dec. 23, p. 833), who, rightly, points out that Roentgen's discovery of *x* rays was not a "stumble" by "accidentally fogging a plate" but the result of systematic experimental research while professor of physics at the University of Wuerzburg, Bavaria. Roentgen's original paper, "Eine neue Art von Strahlen" (a new kind of rays), a copy of which is in my possession, was published in the *Sitzungsberichte der Physikalisch-medizinischen Gesellschaft zu Wuerzburg* (Proceedings of the Wuerzburg Physico-medical Society), December, 1895.

Payment of Doctors in Mental Hospitals

"A.M.O." writes: The letter in the *Journal* of Oct. 28, 1944 (p. 579), raises a matter which should be of paramount importance to medical officers in mental hospitals. A matron in a large hospital may now receive £600 salary and, in addition, emoluments valued at £200. The average salary of a medical officer is £400 to £500. The cost of qualifying in medicine is now about £1,500. Substantial increases in remuneration have been received by the nursing and clerical staffs. This service may become even less attractive to medical men unless the scale of salary is raised and the conditions in general improved.

Headache and "Acute Abdomen"

Mr. D. G. WILSON CLYNE (London, W.1) writes: I was interested to read the note from Dr. T. L. Crawhall (Jan. 13, p. 70) on headache in relation to the acute abdomen. The crux of the whole matter seems to be the exact meaning of the expression "acute abdomen." If one considers acute salpingitis to be a localized type of acute abdomen, then I cannot agree with his aphorism, "An acute abdomen with a headache is never an acute abdomen." During the first two years of the war I was called upon to perform all emergency operations in a large county hospital as an E.M.S. surgeon. This departure from my normal type of work gave me ample opportunity of noting the incidence of headaches, particularly in relation to acute appendicitis. I entirely agree with Dr. Crawhall's aphorism in so far as it applies to this condition, and would even go further and state that on no occasion in a large series of acute appendices did I encounter headache as one of the cardinal symptoms. This cannot be explained by the fact that I omitted to question the patients as to the presence or absence of this symptom; the contrary was the case. In gynaecological practice I have often been impressed by the frequent association of headaches with both salpingitis and pyelitis, and some time in the past I think that I must have encountered another aphorism which runs rather like this, "Abdominal pain and headache in a woman, of acute onset, suggest that she is suffering from either pyelitis or salpingitis." I have repeatedly found the presence of headache of value in the differential diagnosis between salpingitis and appendicitis, and would even say that there is only one really common acute abdominal condition with which headache is often frequently associated—namely, salpingitis. In fact the presence of headache in a woman with an "acute abdomen" should make one consider very carefully before performing a laparotomy.

Coarse Tremor in the Elderly

Dr. W. N. LEAK (Winsford) writes: In "Any Questions?" (Jan. 13, p. 67) your contributor says: "I cannot suggest any medicinal treatment which will help these patients"—i.e., elderly people with a coarse tremor. In 1935 (*Journal*, 1, 1097) I mentioned that prominal might "possibly find its most distinctive use in the control of tremors of various sorts, for many of which there is at present no effective medication." Experience since then has confirmed my opinion, and in the coarse tremor of the aged prominal (phemitone) sometimes produces dramatic improvement. For example, an aunt of mine, who could barely manage to drink her tea using both hands, within a week of commencing prominal was pouring out tea with one, to her great satisfaction.

Peptic Ulcer

Dr. P. K. MUSPRATT (Pleasington) writes: There appear to be many contributory factors in the aetiology of peptic ulcer, but I should like to stress one which is often ignored—namely, the ingestion of over-hot liquids. Digestive trouble is particularly prevalent among bus drivers and conductors, and I suggest that this may well be due to their consuming very hot tea which they have to drink quickly owing to the short time they have at the terminus. As the drivers appear to suffer more than the conductors the sedentary nature of their occupation may play some part. Women probably have more time and therefore drink their tea when it is cooler, especially as they take, as a rule, more sugar and milk, which cool the tea. The discomfort resulting from hot fluids is often not associated with its true cause, as it comes on a considerable time afterwards and is often associated with a feeling of faintness. I do not, of course, minimize the other contributory causes such as tobacco, alcohol, and perhaps the fumes from gas-fires with no chimney outlet, which escape into the room.

Mental Hospitals

Mr. J. P. SPENCER WALKER (Hove) writes: Dr. Otho FitzGerald (Dec. 2, p. 744) objects to the word "asylum," preferring mental hospital. He states that such institutions "are no longer merely places of rest and detention but provide active and specific forms of treatment." The word "asylum" is a beautiful word meaning sanctuary or place of refuge, and the word "hospital" means a place for the reception of guests, but neither in their original sense had anything to do with medical treatment—for example, St. Mary's and St. Bartholomew's Hospitals at Chichester. The former is still an almshouse, and so was the latter until recent times. The change from "asylum" to "hospital" was made owing to the debasing in the public mind of the former word.

Sensitiveness to Strychnine

Surg. Lieut. CAREY BAKER, R.N.V.R., writes: Dr. D. R. C. Shepherd's account of his case of sensitiveness to strychnine (Nov. 25, p. 694) recalled to mind a similar happening in my own experience. A married woman aged 36, a cook by practice, had been under my care for a week suffering from a heavy cold. On returning to work she felt rather listless and asked for a tonic. I gave her a mixture of iron and strychnine containing two minims of liq. strych. hyd. to the dose. I also was hastily summoned to find the patient collapsed, cold, pale, and almost pulseless within ten minutes of taking the first dose. Though I was sceptical about the attack being due to such a small dose of strychnine I could discover no other cause and was not prepared to experiment further. There was no previous history of sensitivity to the drug, but then, as the patient said, she seldom had to take any medicine. Fortunately no ill will was felt, the patient quickly recovered, and was given a strychnine-free mixture.

Gauze Impregnated with Paraffin

Messrs. JOHNSON AND JOHNSON (GREAT BRITAIN) LTD. write: We would draw attention to the article which appeared on page 856 of the *B.M.J.* of Dec. 30, 1944, entitled "Curtain Net Impregnated with Paraffin." This product was manufactured by us for many years under the name "porowax" gauze, and was demonstrated extensively on several occasions at the London Medical Exhibition and on one occasion at the British Medical Exhibition. It was listed and illustrated for several years in our catalogue, and we would be grateful if due acknowledgment could be made to these circumstances in your *Journal*.

Corrigenda

The duration of pregnancy in three of the cases of "A.I.D." reported in the *Journal* of Jan. 13 (p. 43) is given as "45 weeks." The sentence should, of course, read "terminated successfully at 35 weeks."

The medico-legal note headed "A Fatal Overdose of Carbachol" published on Jan. 13 stated, incorrectly, that the report of the inquest appeared in our issue of July 4, 1944. The date should have been July 4, *1942* (p. 28).

LONDON SATURDAY FEBRUARY 3 1945

THE CLINICAL CHARACTERS OF PAIN*

BY

WALTER GANADO, M.D.Malta, B.Sc.

Acting Professor of Physiology, Royal University of Malta

in has been defined as a specific feeling that protects from xious stimuli. Pain is, however, not a single feeling. It is ther a group of distinct feelings, each of which has clinical aracters of its own. Thus pain of the skin is different from in of the muscles. Each type is related to a definite group tissues. Examination of this relation is of theoretical and agnostic interest.

Severity

The general level of severity of a pain can be influenced much by the patient's personality and surroundings that reliable conclusions can be reached from its study. The amination of the relative sensitivity of tissues is more useful. ot all tissues are equally sensitive. Some, like the cornea, e exposed to injury, and yet the effects can be serious even ough the injury be slight. These tissues, as may be expected, ve a high degree of sensitivity; but the sensitivity of ordinary sues is much lower. It would be very inconvenient if the nsitivity of all tissues were high. When the injury is so ild as not to be of any consequence it does not reach nsciousness. On the other hand, if the stimulus, even though ild, persists too long or if the tissue is still suffering from e after-effects of a previous injury, further damage of any gree can be dangerous and the threshold of pain is then wered. The sensitivity of a tissue is not a constant, but a riable that changes with the previous history of the injured sue.

Thus if the skin is damaged in any way there develops after short interval a diffuse area of tenderness which surrounds e site of injury. This area is hypersensitive to stimuli of at, cold, pressure, etc., that from their degree would not rmally be enough to produce pain. This hypersensitivity limited specifically to the organs of pain; for example, e organs of touch are not affected, as can be tested by y's hairs. The central mechanism of this hyperalgesia is timately segmental, but the nerve distribution within the in is such that the area of tenderness around the site of jury follows a geometrical, not a segmental pattern, being ncentrical around the injured spot. It is never referred to a stance.

In the deeper tissues hyperalgesia occurs also. When 2 c.cm. a 6% hypertonic saline solution was injected deep in my ceps muscle, after five to six minutes there appeared definite nderness even on slight pressure over the site of injection. ter an interval the tenderness was more diffuse and was t over a large part of the posterior aspect of the arm. The nderness was not equally marked everywhere. Over the jury it was easy to elicit and to locate; at some distance was present as hypersensitive spots which kept changing eir place from time to time, especially after active exercise. ese spots were not easily located, and were vaguely circumcribed. Active exercise of the arm re-exacerbated the tenderss when it had become milder after rest.

Similar tenderness is met with in numerous clinical conditions, d its presence in a diffuse form may mislead as to the al site of injury. It has the same distribution as with deep in, it has not a geometrical but a segmental pattern, and can even be referred to a distance. Thus deep tenderness in diaphragmatic pleurisy may accompany pain over the neck and shoulder.

Power of Discrimination

The tracing of the curve of a pain's intensity against time is called the curve of time-intensity of that pain. The type of curve is influenced by the activity of the stimulus, but depends upon the properties of the injured tissue. In fact, the same stimulus applied in the same manner produces different curves in different tissues.

When 0.5 c.cm. of a 6% hypertonic saline solution was injected intradermally into my forearm it caused pain that was felt very early and rose very rapidly to its maximal intensity. When an equal amount of the same solution was injected into my triceps muscle the pain took some seconds to appear and some seconds more to become maximal. Again, when a pin-point is applied to the cutaneous surface the pain is immediate and maximal from the very start; it fluctuates in intensity with the variations in pressure of the pin, and disappears as soon as the pin is taken away. When, however, the skin and the subcutaneous tissue of a zone over the triceps muscle were anaesthetized by 2% novocain solution and a needle was inserted through this area into the triceps, the pain was not immediate. It took several seconds to appear; it increased slowly in intensity, did not fluctuate with the movements of the needle within the muscle, and persisted long after the needle had been removed. While skin pain portrays in its intensity curve the activity of the stimulus, muscle pain is not a faithful index of this activity, and is in this sense non-discriminative.

In the deep tissues discrimination is also defective in the power to distinguish as separate two distinct stimuli. When the overlying skin was anaesthetized two separate injections of 0.5 c.cm. 6% saline into my triceps, four inches apart, were not felt as distinct sources of pain. This was noticed whether the injections were given simultaneously or at an interval of 30 seconds from each other. With two injections the distribution of pain was somewhat different from that with a single injection; but the pain from either injection was so diffuse and its distribution overlapped so much in the area of distribution of the other pain that it was impossible, even with an effort of will, to detect two separate foci.

Power to Locate.—The power to locate the site of the injury from the pain that is felt depends upon the type of tissue injured. It is perfect on the cutaneous surface, but gets progressively more defective the deeper the tissue, as will be discussed later on.

Quality

Quality is the distinctive character of a sensation; but it is a character that cannot be described. We can, for example, say what physical stimulus carries the feeling of green vision or which objects look green, but we cannot describe green itself. Similarly with pain. We can say which stimuli cause a certain type of pain or we can compare it with another familiar pain, but we cannot describe the pain itself (Lewis, 1938). We use as terms of comparison a familiar pain which is related to some part of the body, as when we say that the pain feels like a tummy-ache; or we compare pain with that which is related to a function, as when a mother compares her pain to a labour pain. Much more commonly we make comparison with a pain that is provoked by a familiar stimulus, as when we call a pain "burning" because the same type of pain is produced by a burn. This is reflected in our terminology of pain (Lewis, 1938).

---

* From a paper read in 1943 to the Malta (Over-seas) Branch of e British Medical Association

This common method of comparison based on the stimulus too often conveys the false impression that the characters of a pain are a function of the stimulus. If the quality of a pain were a function of the stimulus we could not explain why the same stimulus applied in the same manner should give pain of a different quality in different types of tissue. Thus the injection of 0.5 c.cm. of 6% hypertonic saline produces burning in the skin, aching pain in the muscles, and pain of a different quality in the subcutaneous tissue of the forearm. The quality of a pain is a function of the injured tissue. The same tissue will always give pain of the same quality, whatever the stimulus (Lewis, 1938). To become convinced of this one must take every precaution to obtain the pain in as pure a quality as possible. It is necessary to avoid stimuli that excite more types of tissue at a time; to eliminate all concomitant modifying feelings of touch, pressure, stretch, and temperature; and to use stimuli that act for equal intervals of time when comparing two tissues.

Types of Somatic Pain

From the quality and from other characters of their pain it is possible to classify human tissues into groups. Neither anatomical structure nor physiological function determines to which group a tissue belongs. Thus the injection of hypertonic saline within the triceps muscle of a patient who had post-undulant arthritis of the hip-joint produced pain which he regarded as of the same quality as the pain in his thigh. Injection of 0.3 c.cm. of 6% hypertonic saline within the tendon of my flexor carpi ulnaris gave pain whose quality and characters resembled the pain from my triceps but was different from pain provoked by an equal dose of the same solution injected at the surface of my tendo Achillis about an inch above its insertion. At least three types of somatic pain can be distinguished: (1) Surface pain, from the cutaneous and mucosal surfaces. (2) Subsurface or intermediate pain, from the subcutaneous tissues (where these are thin), from the submucosae, and from some adjacent structures when the subcutaneous tissue is very thin. (3) Deep pain, from muscles and from all the other sensitive deep tissues in general.

Surface Pain

If pain from the skin is very short it is pricking, if prolonged it is burning; the difference between the two being only of duration, not of quality (Lewis, 1938). Pricking can be elicited from exactly the same spot and by the same stimuli that give burning when the injury is prolonged. Pricking and burning are the only sensations of pain from the normal skin. They are generally modified by concomitant subcutaneous pain or by touch, temperature sense, etc., but if these feelings are eliminated the skin is unable to respond to any sort of injury except by pricking or burning. Burning is the sensation which we associate with excessive heat, but it is definitely not the response of the temperature organs to the excess of heat. Excessive heat produces burning because it produces prolonged injury and stimulates the cutaneous organs of pain. Also cold, if intense enough to cause injury, produces burning, as can be evidenced by prolonged immersion of a finger in a freezing mixture, by a cold wind, or by chilblains. Pricking or burning is absent in injury to the skin only if the cutaneous organs of pain are not functioning on account of destruction or otherwise. On the other hand, if the lesion is only superficial, as in a mild burn, no other pain will be added.

Itching

Injury to the skin can also produce itching, but for itching to appear the stimulus must act on a skin that is hyperalgesic. Itching is not elicited from a normal skin. In a skin that has been already injured, as in dermatitis, it can be provoked even by very slight added injury, such as scratching, the application of ointments, changes of temperature, etc. The quality of itching cannot be distinguished from the pricking-like pain which is produced by droplets of strong acids or of other irritants if they fall on the skin in size so minute as not to be felt. is suggested that itching is only a variety of surface pa which is completely free from any other sensation and whic occurs in skin that is hyperalgesic from a previous injury.

Other Characters of Cutaneous Pain

The functions of surface pain are obviously directed towar providing enough information about the offending stimulus make adequate defensive reactions possible. In fact, all i characters tend to promote accuracy: the pain is very we located; it is localized and never referred to a distance; t power of discrimination is good. The protective reflexes pr voked by the injury are all directed with considerable precisi towards the elimination of the stimulus or towards the wit drawal of the injured part from danger. Typical are t scratch and the flexor reflexes. If the stimulus is adequa there is an added systemic reaction which invigorates the mi and the body and enables the individual to face the dange Sympathetic activity is then increased; the mind is on the ale and emotions of anger, rage, fear, etc., may appear. The reactions are sometimes provoked purposely by inducing surfa pain. Thus they occur when we stimulate horses by whippi or during certain forms of treatment of a fainting fit.

Pain from the Mucosae

Not all the mucosae are sensitive. Those that are dista from injury of external origin are insensitive. When, howeve a mucosa is sensitive its pain is pricking or burning, as c be expected when we consider that a mucosa is a surfac Itching, pricking, and burning are familiar results of inju to the stratified mucosae of the conjunctiva, mouth, thro anal canal, urethra, labia, and lower vagina. Whatever t stimulus, the pain is always of the same quality. Thus burni in the mouth occurs whether the injury is due to hot fo or to a chemical irritant, catarrhal inflammation, ulcer, atrophy from a deficiency disease.

The oesophageal mucosa is normally insensitive to t presence of gastric juice, which regurgitates even during norm digestion. When, however, the mucosa is injured from a cause it becomes sensitive to further injury. Its pain is th burning. The pain occurs during the ingestion of irritan or during digestion when acid juice regurgitates. It is th spoken of as heartburn. It is diffuse, and is located vague behind the lower part of the sternum.

The pain of cervical erosion is not burning; but the muco of the cervix is so much adherent to the underlying tissu that the pain of cervical erosion is probably due to the subjacent tissues. The mucosa itself is probably insensitiv it does not respond to pin-prick. Equally the pain of t nasal mucosa, when provoked by ordinary stimuli, is d chiefly to the underlying periosteum to which the thin simp mucosa is adherent. If stimuli that act only very superficial are used, as in the inhalation of ammonia or on the instillati of hypertonic drops, the pain elicited is purely pricking burning. The nasal sinuses and the middle ear are usual described as having a sensitive mucosa; but probably t mucosa is insensitive and the pain which is felt is perioste Pain from the larynx is pricking or burning.

The transitional mucosa of the urinary bladder also gi pricking or burning pain, but its behaviour is peculiar. T mucosa over the fundus is innervated from the lumbar segmen while that over the trigone is innervated from the sac segments. The sensitivity varies accordingly. When cystos[illegible] patients, under local analgesia, were examined in my presen it was shown convincingly that the mucosa of the fundus w completely insensitive and that pain from the fundus cou be elicited only from the structures underlying the muc In contrast to this the mucosa of the trigone was very sensiti Crushing of a tiny fold between forceps produced pain wh quality was unmistakably burning. However, the pain w not located to the bladder but to the surface of the perineu Pain of a different quality was obtained only if the stimul also excited tissues that lie beneath the mucosa.

Subsurface or Intermediate Pain

The tissues that lie immediately beneath the skin or benea the mucosae give pain whose characters differ from those surface and of deep pain.

There seems to be a difference in the quality of the pain. Subcutaneous injury to a region where the subcutaneous tissues are thin, as over the forearm, gives pain of a quality which is distinct from pricking, burning, or aching. However, it is possible that this difference in quality from deep pain is felt only because it is modified by concomitant surface pain. When testing the subcutaneous tissues it is desirable to eliminate cutaneous pain, but it is not easy to do this convincingly without interfering with subcutaneous sensitivity. If unguentum anaesthesinae be rubbed over an area of lightly scarified skin till this feels numb to a pin-prick, or if an intradermal wheal be produced by a solution of novocain and adrenaline, a subsequent injection of hypertonic saline in the underlying subcutaneous tissue can be presumed to give pain that is unmodified by cutaneous pain. Its quality differs somewhat from deep pain; it is, if one may say so, of a higher tone.

Where the subcutaneous tissues are thick, as in the female mammary region, pain of the inner strata is not described as different in quality from deep pain. On the other hand, where the subcutaneous tissues are very thin, so that the skin is adherent to the deep fascia and underlying structures, the pain from these structures is also different from deep pain. Thus the periosteum over the tibia or over the knuckles, the outer fibres of the tendo Achillis, and the fibrous web between two fingers give pain whose quality differs from deep pain (Lewis, 1938).

Just beneath the body surface there is a second coating of tissues, pain in which is distinct in character from deep pain and complementary to surface pain in detecting injury of external origin. More than in quality, this intermediate type of pain differs from deep pain in its power to discriminate and to locate the injury. The pain is somewhat diffuse, but its diffusion is always limited to a narrow zone around the injury. It gets wider when the tissue is deep, but it is not referred to a distance. The reflexes provoked through it reinforce the surface reflexes in producing brisk movements, as can be evidenced by the technique adopted for the Babinski response.

The submucosae and some other structures to which the mucosa is adherent when the submucosa is very thin, as in the muco-periosteum of the nasal sinuses, are the seat of pain which is also distinct from deep pain. Thus pain from inflammation within a nasal sinus or within the middle ear is different in its quality from surface and deep pain. This pain, however, is not easily located. When the submucosa lies in a cavity that is at a distance from injury of external origin the pain is referred to an area over the surface which is innervated by the same segment.

Deep Pain

Pain from deep tissues has an aching quality. It is common to muscles and to all the other sensitive deep tissues in general.

Deep pain raises the alarm when injury reaches a deep locality, but it does not by itself furnish any useful information to help in eliminating the stimulus. It is non-discriminative. It is unable to disclose more sources of pain even if these are considerably distant from each other. It starts late, persists long, and does not portray the activity of the stimulus by fluctuations in its intensity. The pain is always very diffuse. It is impossible, from a deep tissue, to get pain which is felt only at the site of injury. The pain radiates to a distance, and this radiation is often extensive. There are several factors which determine whether the pain remains local or radiates extensively. The severity of the injury is important. A stronger concentration or a bigger dose of the hypertonic saline which was injected in my triceps determined different grades of diffusion. The time-interval after the injury is important too. When adaptation to pain starts after a variable interval, the pain becomes restricted to a narrow area; but subsequent injury of any nature, or even active muscular exercise, can not only re-exacerbate the pain but also make it extend to some distance. A very important factor is the depth of the injured tissue. The deeper the tissue the greater is the tendency of the pain to radiate extensively (Kellgren, 1939). The relation of the injured tissue to structures of vital importance, as the spine, is perhaps also important. The nearer the tissue to such structures the more the pain is radiated.

The radiated pain can be as intensive at a distance as over the site of injury. Thus when 2 c.cm. of a 6% saline solution was injected into my triceps the pain in my elbow and forearm was as intense as the pain in the arm. Sometimes the pain is more intense at a distance than over the injury. When 1 c.cm. of hypertonic solution was injected into the upper margin of the trapezius muscle at an equal distance between the head and the shoulder the pain was felt most intensely at the angle of the jaw, so that one would locate the injury much higher than it actually was. In these circumstances one speaks more of the diffused pain than of the pain over the injury, and indeed can ignore the latter pain completely, unless an added factor directs attention to the real site of injury. If the pain is exacerbated by the movements of a joint or by the active contraction of a muscle of which the patient is fully aware, it will be easy for the injured individual to connect the pain with the region that causes the exacerbation. Equally, if deep injury is accompanied by injury to overlying subcutaneous tissues or skin and subcutaneous tissues, the power of these tissues to locate will direct the individual's attention to the site of injury. Thus when 2 c.cm. of hypertonic saline was injected into my triceps by means of a very wide-bored needle through a normal skin, the pain was felt in the arm, elbow, forearm, and even hand, but it could be made out that its source was in the arm. When, however, an intradermal wheal was produced by a solution of novocain and adrenaline and the injection was performed through this wheal with a very fine needle, which was inserted to the same depth as on the previous occasion, the pain had practically the same distribution as before; but, so long as the arm was kept at rest, not even with an effort of attention was it possible to be sure that the pain originated in the arm. When the triceps was made to contract, especially if it was made to contract isometrically against resistance at the wrist, the pain in the arm was exacerbated, and that made the source appear more manifest.

Possibly, pain that is referred from certain viscera is badly located for similar reasons. It has been determined that many viscera are connected by their pain afferents to the centres which subserve the deep somatic structures. These centres can therefore be stirred into activity from either source, so that pain from the viscus and pain from the somatic tissues cannot be distinguished from each other (Lewis and Kellgren, 1939). Thus stimulation of the first lumbar interspinous ligament evokes pain with the distribution and other characters of renal colic, including retraction of the testis; stimulation of the left seventh cervical or of the left first thoracic ligament evokes pain which extends down the arm and cannot be distinguished from angina of effort. In these instances the patient is unable to distinguish whether the pain is visceral or somatic, or to locate its source. In either case there is no added factor which can attract his attention to the injured somatic spot or to the disturbed viscus. The patient will hence speak only of a diffuse deep pain along the segment.

The reflexes that accompany deep pain, far from provoking brisk defensive movements, produce tonic contractions and quiescence. They aim more at resting the injured part and protecting it from subsequent injury than at eliminating the offending stimulus. The contraction is slow in onset and gets maximal only after a considerable interval. Sometimes the rigidity is slight and passes unobserved, the patient limiting his movements more from fear of exacerbating the pain than from inability to move on account of spasm. When, however, the injury is appropriately located as near a joint, near a cavity, or near a vital organ, the spasm may be such as to resist even deep anaesthesia and hamper operative intervention. It may be localized, but when severe it may form a definite barrier around the greater part or the whole of the injured segment, and may even occur at a distance from the injury. Thus the cremaster may contract when the injury is located in the spine.

The general reactions that are associated with deep pain tend equally to inhibit activity. Far from being invigorating, they cause mental and physical depression, with diminished knee-jerks, low blood pressure, etc. If the injury is severe, especially if it is diffuse and located within the trunk or very near to it, the full picture of "nervous" shock appears.

The Segment

However diffuse or referred deep pain may be, its distribution follows always a segmental pattern (Kellgren, 1938). The same pattern fits the deep tenderness as well as the muscular rigidity that accompanies the pain. If in embryonic life the injured tissue has migrated from its first relative position to another segment, the pain still extends along the segment from which the tissue has migrated and to which it has remained attached by its innervation. This is exemplified typically by the pain from a lesion to the central part of the diaphragm whose area of diffusion lies in the area of distribution of the third and fourth cervical nerves.

Within the affected segment the direction of the diffusion of deep pain is determined more by the level of the segment than by the situation of the injured spot in the segment. Thus in a thoracic segment the pain is felt anteriorly even if the injury is situated as far backwards as an interspinous ligament. In the last thoracic and in the upper two or three lumbar segments there is hardly any space anatomically for an anterior diffusion, and deep injury at this level causes backache. In the upper cervical segments the direction is predominantly posterior to the occiput; in the lower cervical it is predominantly anterior to the arms.

This extension of pain in an anterior or posterior direction occurs the same whether the pain is visceral or somatic in origin. As already stated, renal colic and interspinous injury give pain with identical distribution. Backache can be caused by a lesion in a pelvic viscus or in a somatic structure. With thoracic or abdominal pain there is a tendency to look for visceral lesions and to forget somatic causes; and, in lumbar pain, to look for somatic and forget about visceral lesions. This tendency probably arises from the greater frequency of visceral lesions in thoracic or abdominal pain and of somatic lesions in lumbar pain; but it is wise to be "segmentally minded" and to investigate all structures within the segment in every case.

Visceral Pain

The viscera lie, as a rule, so deep within the segments that they are well protected and do not therefore respond to the stimuli that provoke pain ordinarily in the somatic tissues. Many viscera are completely insensitive, and any pain that is associated with them is caused by an extension of the lesion to adjacent tissues, as to the parietal peritoneum or to the retroperitoneum. Other viscera are sensitive, but their stimuli must be appropriate to them, and their pain has the same characters and is probably furthered by the same mechanism as somatic pain. Embryologically these viscera are intimately connected with the somatic tissues. They arise entirely from the mesoderm, from each side of the segment; they are paired, or have been paired during some period of their embryonic life. Examples are the kidneys and the heart.

There is still another group of viscera. These are hollow organs which have never been paired, but have had always a mesial attachment and have included ectoderm in their cavities. Pain from these organs has distinct characters. It is exemplified typically by the pain of obstruction from a stenosing carcinoma of the colon. The appropriate stimulus is related to the spasm, which is a response to the stretching provoked by the obstacle. This pain, in quality, is not different from deep pain, and can be simulated by injecting hypertonic saline in the abdominal rectus muscles, but it is never accompanied by muscular rigidity or by tenderness of any kind; hence compression of the wall and active movements are not resented, and the patient may press his abdomen, bend, and writhe about restlessly in a vain attempt to obtain relief (Morley, 1937). The pain is diffuse, but even when maximal it remains always mesial and never extends beyond the abdominal wall to the limbs. Its distribution is segmental (Brown, 1942). It is referred to the level from which the viscus migrated in embryological development. It is epigastric for the stomach, duodenum, and gall-bladder; umbilical for the small intestine and appendix; hypogastric for the colon and urinary bladder. Pain from the rectum is felt vaguely about the site of the viscus.

Pain from Nervous Tissues

Before concluding it must be mentioned that clinically there is yet another type of pain derived from a lesion to the nervous tissues, central or peripheral. In the sense that it is never meant to serve a defensive purpose this pain is not physiological, and therefore is not considered further here.

Conclusion

From their clinical characters we can distinguish types of pain each of which is related to a definite group of tissues. These tissues have in common their relation to the body surface.

There must be in each segment a complex mechanism which presides over the manifestations of deep pain in that segment. This mechanism can be set in motion by certain visceral as well as somatic afferents. Their connexions must be such that the whole or the greater part of the mechanism can be set in motion even by limited injury; hence the pain is distributed widely and lacks discrimination. More superficial tissues have connexions which are more limited, while the connexions of the hollow abdominal viscera which have a mesial attachment in their embryonic life are distinct.

The connexions from the skin must be entirely different, as the pain differs not only in discrimination, power of location, and type of reflexes provoked, but also in quality.

SOME SOCIAL ASPECTS OF BURNS IN GLASGOW

BY

ALEXANDER BROWN,* M.B., M.R.C.P.Ed.

E. LEWIS-FANING,† B.Sc., Ph.D.Lond.

AND

MARTIN M. WHITTET, M.B.

The Magnitude of the Problem

The present high incidence of accidental burns in the civilian population, causing incapacity often of long duration, is a problem of great importance to the community in a state of total war. The study of the factors related to the occurrence of these injuries is of immediate interest. It should reveal also whether or not the high incidence may be expected to continue with the resumption of more normal conditions.

The progressive increase in the numbers of cases of burns admitted to hospital in Glasgow over a period of 100 years has been shown clearly by Dunbar (1934); it is probable, as Dunbar himself suggests, that part of this increase was due to a greater liability or inclination of burned patients to be treated in hospital in the latter part of the period surveyed, but that can hardly be the only factor concerned. Thus at the beginning of the period—in the decade 1833–42—the maximum number of cases admitted to the Glasgow Royal Infirmary in 12 months was about 80. At that time the Royal Infirmary was the only Glasgow hospital to which patients with burns were admitted. In the last decade considered by Dunbar—1923–32—a level of about 320 admissions in 12 months was reached, in spite of the fact that by this time two other large voluntary hospitals were treating these injuries. In the 10-year period 1933–42 a maximum yearly admission of 327 cases was attained. In the 14 months from June, 1942, to Aug., 1943, 1,803 cases of burns were treated in the burns unit of the Glasgow Royal Infirmary, and, of these, 303 (16.8%) were admitted to the wards.

The following points should be noted as a preliminary to the considerations given later: (*a*) The Royal Infirmary Glasgow, is situated in an industrial area and might therefore be expected to deal with a high proportion of industria accidents. (*b*) The large numbers of infants and children treated for burns at the Infirmary do not represent all the

---

[*] Working with a part-time grant from the Medical Research Council.

[†] Member of the Medical Research Council's statistical staff.

cases of burns in the district. Some would be treated at the Royal Hospital for Sick Children. (*c*) There is no reason to suspect preferential admission of one or the other sex to the burns unit of the Infirmary. (*d*) No cases of burns due to enemy action are included in this series.

Incapacity due to Burns

The 1,803 cases of burns are responsible for a considerable amount of incapacity among the wage-earners of the community. Analysis of the period of disablement in the various age groups of the 303 cases admitted to hospital is made in Table I. The figures indicating the disablement period include the total time spent in hospital and an average of 7 days during which outdoor treatment was given. This is a very conservative estimate.

TABLE I.—*Age and Sex Distribution of 303 Cases of Burns admitted to Glasgow Royal Infirmary*

Age (Years):	0–10	11–20	21–30	31–40	41–50	51–60	60+	Total
Males . ..	77	23	13	22	13	11	8	167
Females	65	19	13	12	9	10	8	136
Total ..	142	42	26	34	22	21	16	303
Average period of disablement (days) per case	34·2	36·1	44·6	39·4	38·8	39·2	32·9	

In the age group 15–60 years the immediate result was a loss to the community of an average of 3,180 man-hours per month. In addition an average loss of 2,900 man-hours per month (calculated on the basis of an 8-hour working day) occurred in 668 cases of this age group treated wholly as out-patients. This loss of a total of 6,080 man-hours per month does not include a period of partial incapacity, the extent and duration of which it has been impossible to estimate; nor does it take account of the remote effects of the more severe burns sustained during the first 15 years of life, or the remote effects, psychological and material, of severe disfigurement.

Mortality due to Burns

Some idea of the magnitude of the problem can be obtained from the recorded mortality figures in relation to burns in Britain, and the United States of America (Table II). (The figures for Britain were obtained from the Reports of the Registrar-General, 1937; those for America from the U.S. Bureau, Vital Statistics, Special Reports, 1939, **7**, 77, quoted by McClure, 1939). The increasing numbers of burns noted by Dunbar, together with the attendant disability and these mortality figures, suggest that there is every prospect of the maintenance of this high incidence.

TABLE II.—*Mortality from Burns in Great Britain and the U.S.A.*

	Scotland, 1937	England and Wales, 1937	U.S.A., 1939
Population	4,976,610	41,031,000	128,000,000
Deaths from burns ..	256	1,318	6,240
Death rate per 10,000	0·51	0·32	0·49

All differences mentioned in the present report have been tested for statistical significance, and are unlikely to have arisen as the result of chance unless it is specifically stated.

Aetiological Factors

Analyis of the cases treated at the Glasgow Royal Infirmary from June, 1942, to Aug., 1943, provides the following information.

TABLE III.—*Age Incidence*

Age Group (Years)	Population, 1931 Census	%	Total Burns	%	Rate per 1,000	Total Admissions	% Total Cases
0–	225,334	20·7	737	41	3·28	142	19·3
11–	192,173	17·7	392	22	2·05	42	10·7
21–	188,215	17·3	216	12	1·15	26	12·0
31–	153,856	14·1	181	10	1·18	34	18·8
41–	130,875	12·0	150	8	1·15	22	14·7
51–	107,355	9·9	77	4	0·72	21	27·2
61+ ..	90,653	8·3	50	3	0·55	16	32·0
All ages ..	1,088,461	100·0	1,803	100	—	303	16·8

Age.—Of the total of 1,803 cases 41% occurred in the first 11 years of life, the proportion falling with each successive decade. Only 3% of the cases occurred in persons over 60 years of age (Table III). The very high incidence of burns in infants and children is shown by the fact that 53% of the cases occurred in the first 15 years and 25% in the first 3 years of life. On the basis of the age distribution of Glasgow's population in 1931, no excess of burns in children could have been suggested if only 20% had occurred in the first 11 years of life. The figure is, however, so much greater than this (41%) that it is probably significant in spite of changes in the age distribution due to the outbreak of war. With regard to the age distribution of cases admitted to hospital, Table III also indicates that the admissions in each age group were not proportional to the total cases. Fewer patients under 21 and more of those over 21—particularly in the ages above 40—were admitted to hospital. These differences are significant, and the general impression is confirmed that, while the incidence of burns is higher at the younger ages, the injuries are more serious in the older patients.

Sex.—Of the 1,803 cases 56.3% were males and 43.7% females—a ratio of 128:100. Of the 303 patients admitted to the wards, 55% were males and 45% females—a ratio of 123:100. Comparing the age distribution of male admissions with that of females, no real difference is demonstrable. In Dunbar's series, until 1865 the ratio of 200:100 obtained, and in the last decade considered by him the ratio was 100:100. Even if males and females were equally represented in the population of Glasgow it would be valid to deduce from the above figures an excess of male patients. But the 1931 Census figures show that females were slightly more numerous (93:100), and the withdrawal of men to the Services has probably emphasized the difference. It is concluded, therefore, that burns are more frequent among males than among females at every period of life, that this is equally true whether the cases are mild or severe, and that in these respects the position has altered but little in the last 10 years.

Cause of the Burn.—Information as to the cause of the burn was available only for patients admitted to the wards (Table IV). It is of interest to record that 13.9% of the domestic burns were due to hot tea.

TABLE IV.—*Causes (303 Cases)*

Type of Burn*	Cases	% Total	% Domestic
Industrial	52	17·2	—
Domestic	251	82·8	—
Scalds	*132*	—	*52·6*
Fire	*107*	—	*42·6*
Petrol	*8*	—	*3·2*
Electric	*4*	—	*1·6*

* No case of burn from enemy action or from conflagration is included in this series.

Contributing Factors.—The chief intrinsic factors apart from age and sex are mental. They include epilepsy, alcoholism, and insanity with attempted suicide. The incidence of these factors in the admissions is shown in Table V. Mental dullness was noticed in many cases, but in the absence of reliable criteria for its assessment no accurate statement can be made on this point. The influence of these factors is more accurately shown in relation to the number of burns in adults. The term "alcoholism" refers here only to a degree of intoxication amounting to stupor at the time of burning. Many patients had taken alcohol in small amounts, and its relation to the accident was difficult to assess.

TABLE V.—*Contributing Factors in 303 Cases admitted to Hospital*

	Cases	% Total	% in Patients over 15
Epilepsy	12	4·0	11·7
Alcoholism	6	2·0	5·9
Attempted suicide	2	0·7	1·9

Time of Burning.—The time of sustaining the burns in 1,803 cases is shown in Table VI. As might be expected, the majority of patients sustained the injury between 9 a.m. and midnight. In addition, the six-hour period which shows the greatest number of cases is 2 to 8 p.m. The time of burning in relation to age is of particular interest (Table VII). Altogether, 386 (21%) of the 1,803 patients received the burn after 8 p.m. Of this number 287 (74%) were under 16 and 144 (37%) were under 4 years of age. During the remaining part of the 24 hours only 47% of the burns were sustained at ages under 16 and only 22% at under 4. Statistical tests show no difference between the two periods as regards age distribution among patients under 16. But it is a grave reflection that while from midnight to 8 p.m. slightly less than half of the burns occurred in children under 16, yet from 8 p.m. to midnight—i.e., a time when one would expect young children to be in bed and safe—three-quarters of the burns sustained occurred at these young

Table VI.—*Time of Burning in 1,803 Cases*

ages. The last column of the table shows that the proportion of burns occurring after 8 p.m. was highest between ages 1 and 2 (38% of all burns at this age happened after 8 p.m.). The proportion varies between 23 and 30% at other children's ages, but for all ages over 16 combined it is as low as 11.7%.

Table VII.—*Age and Time Distribution (1,803 Cases)*

All ages	1,803	1,417		100·0	386		100·0	21·4

Extent of the Burn.—The average extent of the burn differed greatly in the sexes. This is seen to be due to the large proportion of males with burns of minor degree, and the greater proportion of severe burns in females (Table VIII). Only 13% of the males had burns involving over 15% of the body surface, against 27% of the females. In addition, the average area of the burn was 8% in the males and 14% in the females. The tendency for the more severe burns to occur in the female may be related to the difference in clothing.

Table VIII.—*Extent of Burn in 297 Admissions for which Data were available*

Area Burned (%)	Males		Females	
	Cases	% of Total	Cases	% of Total
0–	90	55	54	41
5–	52	32	43	32
15–	12	7	21	16
30+	10	6	15	11

Deaths due to Burns

In the series of 303 admissions there were 40 deaths. Fatality rates by age and sex are given in Table IX. At every age group the rate is higher for females than for males, and this in itself indicates that the excess fatality rate for females at all ages combined—17.6%, as compared with 9.6% for males—is significant. Using broader groupings, the figures suggest that the fatality rate is much higher at the older ages; but the total number of deaths is too small for valid statistical tests, so that this conclusion must be accepted with reserve.

Table IX.—*Fatality Rates by Age and Sex in 303 Admissions*

Age Group (Years)	Males			Females		
	Cases	Deaths	Fatality Rate (%)	Cases	Deaths	Fatality Rate (%)
0–	77	8	10·4	65	9	13·8
11–	23	0	0	19	2	10·5
21–	13	0	0	13	0	0
31–	22	2	9·1	12	2	16·3
41–	13	1	7·7	9	3	33·3
51–	11	1	9·1	10	1	10·0
61+	8	4	50·0	8	7	87·5
All ages	167	16	9·6	136	24	17·6
0–	100	8	8·0	84	11	13·1
21–	48	3	6·2	34	5	14·7
51+	19	5	26·3	18	8	44·4

When the age distribution of the deaths in this series is compared with that of deaths from burns in Scotland as a whole for 1941[*] no real difference can be demonstrated (Table X).

Table X

Age Group	This Series	Scotland, 1941
0–	17	105
11–	2	21
31–	8	21
51+	13	89
All ages..	40	236

$\chi^2 = 4{\cdot}9$. P = 0·17.

It is possible, therefore, to arrive at a very crude estimate of the number of admissions to hospital from burns in the whole of Scotland. For if 40 deaths arose from 303 admissions, then 236 deaths would have arisen from 1,788 cases of burns serious enough to be admitted to hospital.

The mortality from scalds was lower than that of other types of domestic burn. In 132 cases of scald 9 (6.8%) deaths occurred, whereas 29 deaths occurred in the other 119 domestic cases (24.4% mortality; difference, 17.6±4.5%). Only 2 deaths occurred as a result of industrial burns (3.8% mortality, as compared with domestic 15.1%; difference = 11.3±5.2%).

Summary and Conclusions

This report gives a statistical analysis of 1,803 cases of burns treated in the burns unit of the Glasgow Royal Infirmary between June, 1942, and Aug., 1943, particularly in regard to 303 patients who were admitted to hospital. It is supplementary to the series of papers published in "Studies of Burns and Scalds: Reports of the Burns Unit, Royal Infirmary, Glasgow, 1942–3" (Med. Res. Cncl. Sp. Rep. Ser. No. 249, 1944).

The incidence of burns was high at the younger ages, but the results were more serious in older patients. The incidence was higher among males, but fatality was greater among females.

The injuries were sustained most frequently between 2 p.m. and 8 p.m., but the incidence of burns at a late hour was greatest in the early age groups. Between midnight and 8 p.m. less than half the burns sustained occurred in children under 16, but between 8 p.m. and midnight three-quarters of the accidents occurred at these young ages. The grave social implication of this finding is stressed.

We are indebted to Mr. A. M. Clark, surgeon in charge of the burns unit, for permission to publish these findings; and to Dr. L. Colebrook, Prof. J. W. S. Blacklock, and Prof. M. Greenwood for much helpful criticism.

CHRONIC INTRACEREBRAL HAEMATOMATA

THEIR PATHOLOGY, DIAGNOSIS, AND TREATMENT

BY

G. F. ROWBOTHAM, F.R.C.S.

Surgeon-in-Charge, Neurological Dept., Newcastle-upon Tyne General Hospital

AND

A. G. OGILVIE, F.R.C.P.

Hon. Assistant Physician, Royal Victoria Infirmary, Newcastle upon Tyne

Intracranial haemorrhages may result from rupture either of normal or of diseased blood vessels. Apart from tearing by accidental forces, healthy cerebral blood vessels rarely burst; on the other hand, when weakened by disease or by congenital malformation the walls of a cerebral blood vessel may give way when subjected to normal stresses and strains.

Spontaneous subarachnoid haemorrhage is a well-known cerebral catastrophe, diagnosis readily being made by lumbar puncture. The clinical picture is usually characteristic. A previously healthy young or middle-aged person is struck with a sudden and severe pain in the head which rapidly radiates into the neck and may reach as far as the fingers and toes. Consciousness may or may not be impaired, and when impairment does occur this may be immediate or delayed. Cranial nerve and limb palsies may or may not develop.

---

[*] Latest figures available.

Blood is always present in the cerebrospinal fluid. Such haemorrhages result from the rupture of aneurysms of congenital origin, which most commonly arise from the vessels forming the circle of Willis. They do not result from the weakening of the vessel walls by syphilis or by any other degenerative process. Embryologically, the endothelial element of the cerebral vascular system is laid down first as solid columns of cells, and these columns later canalize to form the blood channels. The mesodermal coats of the vessels are laid down in sheets. Occasionally these mesodermal sheets fail to meet perfectly at the apex of the junction of two vessels, thus leaving a weakness or congenital defect. It is at such a site that the endothelial coat is likely to balloon and rupture even under the forces of a normal blood pressure. An alternative hypothesis on the formation of aneurysms is that they arise from the stumps of primitive vessels which normally completely disappear. Since the aneurysms arise from vessels that lie in the subarachnoid space, it is thought that when they rupture bleeding must always take place into the subarachnoid space. Occasionally, however, a congenital aneurysm may become attached to the brain tissue and rupture intracerebrally, to cause a chronic haematoma with resulting hemiplegia, as the following two cases will show.

Case I

On the evening of Jan. 22, 1943, a woman aged 28 was admitted to the Royal Victoria Infirmary, Newcastle upon Tyne, under the care of one of us (A. G. O.). It was ascertained from a relative that two hours previously, while sitting at a table writing a letter, she had suddenly slumped forwards. At this stage of the episode she was still conscious, and complained of severe pains over the right eye; the left side of the mouth was twisted and the left arm and leg were stiff. Vomiting occurred on two occasions. Previous to the attack she had been in excellent health and had not been subject to headaches.

When first examined in hospital, the woman was found to be in a state of semicoma; the left side of the body was paralysed; both pupils were of mid-dilatation and both reacted briskly to light; the optic nerve heads were not oedematous; the pulse rate, blood pressure, and temperature were normal; and respiration was deep and rapid. A diagnosis of a spontaneous subarachnoid haemorrhage was made, and this was later confirmed by lumbar puncture, the cerebrospinal fluid being heavily stained with blood. Later, special investigations proved that there were no metabolic disturbances resulting from dysfunction of the kidneys, pancreas, or liver. The blood Wassermann reaction was negative. We came to the conclusion that the subarachnoid haemorrhage was due to rupture of a congenital aneurysm situated somewhere on the circle of Willis, and probably on the right middle cerebral artery because of the left-sided hemiplegia.

On the third day after admission to hospital the woman was fully conscious and fully orientated, but the left-sided hemiplegia remained complete; she felt ill and suffered from considerable pain in the head, particularly over the right eye. From this time onwards very little change was noticed, save that occasionally she would become drowsy, when co-operation was imperfect. She complained continuously of severe headaches.

On Feb. 14 papilloedema was noticed for the first time; the hemiplegia was still complete, there being no evidence of any kind of improvement. On Feb. 16 she was transferred to the neurosurgical unit at the General Hospital, Newcastle upon Tyne, under the care of one of us (G. F. R.). At this date the neurological picture was as follows:

The woman was fully conscious and perfectly co-operative. Sight, speech, smell, and taste were normal. The whole of the left side of the body was densely paralysed. There was no sensory loss or any abnormal cerebellar signs. Both pupils were dilated and both reacted to light and to accommodation; there was a bilateral papilloedema of one dioptre. The blood pressure was 130/80.

Case II

During the evening of July 2, 1943, a young man aged 23 collapsed in his seat at a cinema and his friends carried him into the vestibule. Later he was taken home, and arrived there in a state of confusion, complaining of very severe headache. The next day he was admitted to the Royal Victoria Infirmary under the care of one of us (A. G. O.). At this time the man was in coma and the whole of the left side of his body was paralysed. The pupils were contracted and fixed and both eyes were pulled to the right; the optic disks were flat; both plantar reflexes were extensor; the knee-jerks were increased and the abdominal reflexes were absent. The man's head was extended and there was marked neck rigidity.

A diagnosis of subarachnoid haemorrhage was established by lumbar puncture. In the left lateral position the pressure of the cerebrospinal fluid, as measured by manometry, was 240 mm. of water, the normal figure lying between 150 and 50 mm. Further investigations proved that there was no generalized disease of the cardiovascular system, the blood pressure being normal. No metabolic disturbances were found to point to dysfunction of the kidneys, pancreas, or liver. The blood Wassermann was negative.

The next day the man was still unconscious, but less deeply so than on the day of admission; the hemiplegia on the left side, however, was still complete. On July 6, although his mental condition had improved, he was still confused. The pressure of the cerebrospinal fluid was 80 mm. The red blood cells had disappeared from the fluid, but there was xanthochromia. On July 18 the man was still complaining of severe headaches, and the pressure of the cerebrospinal fluid had risen to 180 mm. During the next two weeks his mental condition remained unchanged and there was no improvement in the hemiplegia. On Aug. 2 he was transferred to the neurosurgical unit at the General Hospital, Newcastle upon Tyne, under the care of one of us (G. F. R.). At this time the clinical picture was as follows:

The man looked ill and obviously had lost a good deal of weight. He was confused, but could co-operate in a simple neurological examination. The left side of his body was completely paralysed and the reflexes were typical of those of an upper motor neurone lesion. There was no sensory loss, nor were there any signs to point to dysfunction of the cerebellum. A bilateral papilloedema of one dioptre was present. The blood pressure was 140/95.

Discussion on Diagnosis and Treatment

In the above two cases the diagnosis of an intracranial congenital supraclinoid aneurysm was reasonably certain. Also, because of the hemiplegia, it was obvious that the aneurysms arose either from the middle cerebral artery or from some vessel close to it. From experience it is known that, with complete rest in bed, bleeding in this type of case will usually cease spontaneously and the hole in the aneurysm close by natural processes. Ligature of the internal carotid artery in the neck, although of great value in the treatment of a cavernous or subclinoid aneurysm, is of little use in the treatment of supraclinoid aneurysms. Repeated bleedings, in spite of rest, in ruptures of supraclinoid aneurysms are best treated by exposure of the aneurysm and local ligature or repair by muscle grafts.

It was, however, in the problem of the hemiplegia that we were particularly interested, and we came to the conclusion that the possible causes of the paralysis were as follows: (i) Obliteration of the channel of the middle cerebral artery either by rupture or by thrombosis. (ii) Pressure on the middle cerebral artery by the aneurysm itself. (iii) Pressure on the middle cerebral artery by a localized blood clot in the Sylvian fissure. (iv) Pressure due to an intracerebral blood clot. (v) Hydrocephalus due to blocking of the cerebrospinal fluid pathways.

Some years ago one of us (G. F. R.) saw a young woman who had had a spontaneous subarachnoid haemorrhage, due, no doubt, to rupture of a congenital aneurysm. From the start she was densely hemiplegic; papilloedema developed at a later date. In the belief that there might be a large surface clot compressing the convexity of the brain, the motor cortex was exposed by raising a bone flap. A large subarachnoid blood clot was in fact found and easily removed. Closure of the wound was so made that a subtemporal decompression was provided. After the operation the hemiplegia did not recede and, in spite of repeated lumbar punctures which proved that there was no further bleeding, the decompression continued to bulge. The girl was densely hemiplegic a year later.

In view of this experience, it was thought that some factor other than surface compression was the cause of the hemiplegia in the two cases under consideration. The secondary rise in intracranial pressure, as shown by the delayed papilloedema, was very suggestive of recurrent bleeding, although lumbar puncture proved on several occasions that bleeding into the general subarachnoid spaces had not occurred. In view of our uncertainty of the cause of the secondary rise in intracranial pressure and of the hemiplegia, it was decided to explore the region of the anterior end of the Sylvian fissure wherein the middle cerebral artery and its many branches lie.

Operation Notes and Results

Case I

On Feb. 18, 1943, under local analgesia, a temporal exposure was made through a muscle-split approach (Rowbotham, 1942). A piece of bone about the size of a five-shilling piece was removed. No blood was found in the extradural or subdural spaces. There was no blood clot beneath the arachnoid mater. The brain was bulging, and was obviously under pressure. All the exposed brain tissue was stained a yellowish colour. The upper temporal gyrus was widened and flattened, and beneath it a softening could be palpated with the finger-tip. The frontal gyri were normal.

By means of a brain cannula a large cyst was found at a depth of 2 cm. in the temporal lobe of the brain immediately below the Sylvian fissure. An incision was made into the brain tissue and the cyst opened; this was about 4 cm. in diameter. Its contents were fluid, consisting of altered black-coloured blood, and were easily removed by gentle suction. The wall of the cyst was smooth and, so far as could be judged by the naked eye, was formed by condensed brain tissue. There was certainly no adventitious membrane such as invariably surrounds a chronic subdural haematoma. In the roof of the cyst a small mound of hard blood was firmly attached to the cyst wall. This no doubt marked the site where rupture of the aneurysm had occurred. Also, it was obvious that the parent vessel was the middle cerebral artery or one of its main branches as it lies deep and high in the Sylvian fissure. In order to minimize the danger of further bleeding, the blood clot was covered with a muscle graft. The dura was left open to provide a decompression; the muscle and scalp layers were re-formed in the usual way, drainage of the cyst being maintained through a fine rubber tube for 12 hours.

Immediate Result.—At the end of the operation the woman's condition was no worse. The next morning there was definite improvement; she was much more alert and her attention was better sustained. Already she could make weak movements with her paralysed arm and leg. From this time onwards improvement was rapid, full power in the limbs being regained before the reflexes returned to normal. The papilloedema had receded by the third day. On the tenth day after operation the woman got out of bed, and finally walked out of hospital on March 6—that is, 16 days after operation.

Late Result.—Her convalescence was steadily progressive, and six weeks after leaving hospital she had regained her normal health. Later she became pregnant, and a child was born on Feb. 2, 1944. After the confinement her general health deteriorated considerably; she became extremely nervous, and for a period lost the use of her left arm. In September she went away for a holiday, and on her return had made a complete recovery. She was examined on Dec. 18; she then had no complaints and stated that she was feeling very well. She was a plump, healthy-looking woman, and neurologically there was not a single abnormal sign.

Case II

On Aug. 4, 1943, under local analgesia, a right temporal exploration was made by means of a periosteal slide (Rowbotham, 1942). A square of bone was removed from the anterior half of the exposure. On opening the dura mater no blood or any other abnormal collection of fluid was found in the subdural space. There was no clot in the subarachnoid space. The brain was bulging, and was obviously under pressure. All the exposed brain tissue was stained a yellowish colour. The gyri of the frontal lobe were widened and flattened, and beneath them a softening could be palpated with the finger-tip. The exposed gyri of the temporal lobe were normal.

By means of a brain cannula a large cyst was found at a depth of 2 cm. in the frontal lobe of the brain immediately above the Sylvian fissure. An incision was made into the brain tissue and the cyst opened. The cyst was about 4 cm. in diameter. Its contents were fluid, consisting of altered black-coloured blood, and were easily removed by gentle suction. The wall of the cyst was smooth and, so far as could be judged macroscopically, was formed by condensed brain tissue. There was certainly no adventitious membrane such as invariably surrounds a chronic subdural haematoma. In the floor of the cyst a small mound of hard blood was firmly attached to the cyst wall. This no doubt marked the site of rupture of the aneurysm. Also, it was obvious that the parent vessel was the middle cerebral artery or one of its main branches as it lies deep and high in the Sylvian fissure. In order to minimize the danger of further bleeding, the blood clot was covered with a muscle graft. The dura was left open to provide a decompression; the muscle and scalp layers were re-formed in the usual way, drainage of the cyst being maintained through a fine rubber tube for 12 hours.

Immediate Result.—At the end of the operation the man's condition was no worse. The next morning there was definite improvement. He looked better and said that he felt better. He was much more alert, and his attention was better sustained. Already the hemiplegia was beginning to recede; weak but definite movements were possible in both the leg and the arm. From this time onwards improvement was rapid, full power returning before the reflexes became normal. On the fifth post-operative day there was no sign of papilloedema and the decompression was flat. On Sept. 16 the man had completely recovered from his illness and walked briskly out of hospital.

Late Result.—Some weeks after his discharge from hospital he had a peculiar feeling as if things were receding from him; also the left side of the face began to twitch. He did not lose consciousness, and felt well again in a few hours. A similar episode occurred some weeks later. In Feb., 1944, he returned to his employment as a melter in a steel-smelting works and has worked regularly ever since, no time having been lost because of ill-health. On examination on Nov. 20 he was a healthy-looking man of excellent physique. He had no complaints, and, apart from the operative defect in his skull, which is of little importance, not a single abnormal sign was to be found.

Commentary on the Underlying Neuro-physiological Mechanism

Probably a combination of cerebral shock and widespread arterial spasm accounted for the sudden impairment of consciousness that occurred at the moment of rupture of the aneurysm. The sudden loss of power on one side of the body probably was due partly to the effect of the above two factors and partly to the fact that the blood which should have been passing along the channel of the middle cerebral artery was passing out of the hole in the aneurysm. The deepening unconsciousness and deepening paralysis which further questioning confirmed or established were due to increasing haemorrhage. As the bleeding ceased and as cerebral shock and arterial spasm receded, consciousness to a large extent returned. The mental dulling which remained was probably due to the pressure of the blood that had been extravasated.

On the other hand, even though consciousness largely returned there was no improvement in the hemiplegia in either of the two cases under consideration. Subsequent events, however, proved that the channel of the middle cerebral artery had not been irretrievably destroyed, because full recovery of function finally did take place. Therefore, although we did not know it at the time, the paralysis must have been due either to vascular spasm or to pressure interfering with the arterialization of the motor cortex. Moreover, the ischaemia could not have been complete, because absolute ischaemia even for a few moments leads to irreversible injury and to permanent paralysis of function.

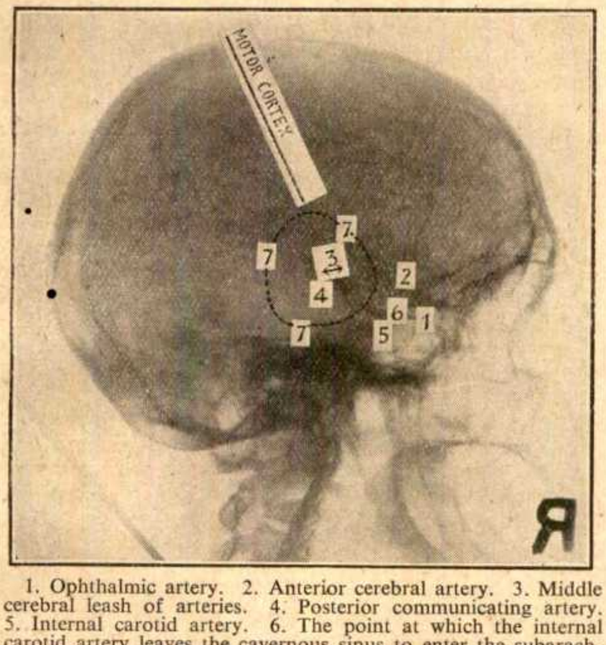
We felt that if the paralysis were due to the pressure of the extravasated blood it would be reasonable to assume that with time the blood would absorb and the paralysis resolve. The opposite, in fact, happened. Instead of the patients slowly recovering, intracranial pressure began to rise after an interval, and it is more than possible that they would have died of rising intracranial pressure. Even if death had not resulted it is very unlikely that recovery from the paralysis would have occurred from natural processes. The secondary rise in pressure was due to the breakdown of the intracerebral blood clot. As the clot broke down its molecular content increased, leading to a rise in osmotic pressure, so that fluid was drawn into the blood clot from surrounding tissues to form a blood cyst of increasing size. This increase in size accounts for the secondary rise in intracranial pressure, which was evidenced in both cases by the appearance of papilloedema and measured in one case by lumbar manometry. After drainage of the blood cyst recovery from the hemiplegia rapidly took place, thus proving the paralysis was due to the pressure of the cyst. The pressure could either have acted directly on the motor cortex by pushing up from below or have acted on the middle cerebral artery, causing partial obstruction of its lumen.

We came to the conclusion that pressure on the middle cerebral artery was probably the mechanism causing the hemiplegia, since recovery from the paralysis was so rapid. In our experience, in cases of hemiplegia due to long-standing compression, relief of the pressure does not lead to such quick improvement as occurred in the above two cases. It might be objected that recovery of function takes place rapidly after the removal of a large extradural blood clot caused by bleeding in the middle meningeal vessels. In such cases, however, the compression has lasted at most for one or two days, whereas in the two cases under discussion the compression and the hemiplegia had lasted 27 days in one case and 32 days in the other.

It might be suggested that at the time of operation it would also have been wise to expose the aneurysm, removing it or ligating its base, as well as draining the haematoma, so as to prevent the recurrence of further haemorrhages. This was not done because opening of the anterior end of the Sylvian fissure introduces the danger of starting up bleeding which is difficult to control, leading to the possible necessity for ligating the middle cerebral artery, with resulting hemiplegia of a permanent kind.

We should like to point out that the nature of the illness was explained to each patient before leaving hospital. The decision not to lead a completely sedentary life—one to have a child and the other to work before an open furnace—was made by the patients themselves. We believe they made the right decision. It is wrong to allow the sword of Damocles to hang too closely above one's head.

The above, so far as we are concerned, is a new venture into the therapeusis of intracerebral haemorrhages, and it has been a very successful one. It must be realized, however, that we chose to operate at the stage of the chronic subdural haematoma and not at the stage of an acute intracerebral haemorrhage. Possibly in those cases of hemiplegia following a subarachnoid haemorrhage it is also wise to operate even when there is no secondary rise in intracranial pressure. We doubt, on the other hand, whether surgery has much to offer in the treatment of ordinary apoplexy or, in fact, in the early stages of a cerebral haemorrhage due to any cause.



1. Ophthalmic artery. 2. Anterior cerebral artery. 3. Middle cerebral leash of arteries. 4. Posterior communicating artery. 5. Internal carotid artery. 6. The point at which the internal carotid artery leaves the cavernous sinus to enter the subarachnoid space. 7. The region in which the chronic cerebral haematomata were found in the two cases described in this paper.

Arteries which arise above the level of the cavernous sinus or clinoid process are classified as supraclinoid aneurysms; they burst usually into the subarachnoid space, rarely into the brain tissue, and sometimes into both. Infraclinoid aneurysms rarely burst either into the subarachnoid space or into the cavernous sinus itself. They do, however, commonly stretch the structures enclosed within the walls of the cavernous sinus, causing in particular a third-nerve palsy.

With its issue for January, 1945, *The World's Children* starts its twenty-fifth annual volume and reverts to monthly publication. According to the leading article, the journal began as a record of the suffering caused to children as a result of the first world war, and in those days it earned the reputation of being, in the words of a Scottish newspaper, "the most melancholy magazine in existence." But there have also been bright spots in the twenty-four years' record of the welfare of children, and they too have had full place in the pages of *The World's Children*. It is published by the Save the Children Fund, 20, Gordon Square, W.C.1.

SULPHANILYLBENZAMIDE, SULPHANILYLAMIDOBENZAMIDE, AND SUCCINYL SULPHATHIAZOLE IN THE CHEMOTHERAPY OF SONNE DYSENTERY

BY

R. SWYER, M.R.C.S., L.R.C.P., D.P.H.

Deputy Medical Superintendent, North-Eastern Hospital (L.C.C.)

AND

R. K. W. YANG, M.B., Ch.B.

Assistant Medical Officer at the Hospital

The treatment of bacterial infection of the intestinal tract by chemical agents was greatly encouraged by the introduction of sulphanilylguanidine (sulphaguanidine) (S.A.G.) by Marshall and his colleagues. The use of the drug is based upon the poor absorption from the gut of a compound soluble enough in the gut contents to be antibacterial to the pathogens concerned. S.A.G. is a rather poor antibacterial substance, and, while effective against dysentery due to Flexner strains, it has proved much less satisfactory in Sonne infections, particularly in effecting bacteriological cure of the Sonne carrier. To meet the difficulty, Brownlee and Tonkin (1941) have suggested the use of sulphanilylbenzamide (S.A.B.); and more recently sulphanilylamidobenzamide (S.A.A.B.) has been introduced. The constitution of these two drugs is shown below:

Sulphanilylbenzamide

Sulphanilylamidobenzamide

A point bearing on the toxicity of these two drugs is that, while their absorption is greater than that of S.A.G., they are acetylated to a less degree. The solubility of S.A.B. varies from 91 mg. per 100 c.cm. in an acid urine (pH 5.8) to 484 mg. in an alkaline urine (pH 7.8). The corresponding solubilities of S.A.A.B. are 112 and 95 mg. per 100 c.cm. (Brownlee: unpublished communication).

We are reporting the results of a clinical trial of S.A.B. on 41 patients of all ages suffering from Sonne dysentery, of S.A.A.B. on 112 patients, and of succinyl sulphathiazole (sulphasuxidine) (S.S.) on a small series of 26 for comparison. The majority were barrier-nursed, while the remainder were nursed in separate glass-walled rooms. In Sonne dysentery the symptoms are usually mild and the disease is more of a nuisance than a danger to the patient. Chemotherapy is therefore directed to the clearance of *Bact. sonnei* from the bowel rather than cure of the "illness," but it does in fact have a beneficial effect in that, in acute cases, within 24 to 48 hours the stools are usually formed, are normal in colour, and contain no blood or mucus when S.A.B. is used. This is true, though to a slightly less degree, for S.A.A.B.

The use of the rectal swab (Cruickshank and Swyer, 1940) and the introduction of desoxycholate citrate agar (Hynes, 1942) have shown that the convalescent carrier is much more common than was at one time believed. In fact, it has been stated that more than half of the clinically infected cases may still be excreting the organism 3 to 4 weeks after onset. Therefore elimination of this carrier state is of the greatest importance. The existence of the carrier being now generally accepted, control untreated cases were dispensed with in the present series and all bacteriologically proved cases were drug-treated. The patients' stay in hospital was divided into a preliminary observation period which averaged 9 days for the S.A.B., 4.5 for the S.A.A.B., and 6 for the S.S. series respectively, a treatment period of 5 days, followed by a second observation period averaging 14.8, 10.9, and 13.2 days for the same three series. As will be seen from an examination of Table II, the length of both preliminary and second observation periods varied considerably. This was caused by such events as concurrent diseases which delayed discharge of bacteriologically free patients, or by other circumstances beyond our control. During the whole of the three periods in the S.A.B. series daily specimens of faeces and rectal swabs (Sundays excepted) were plated on desoxycholate citrate agar, but in the S.A.A.B. and S.S. series bacteriological examinations were done on alternate days. Dosage of all drugs was according to weight of the patient, as shown in Table I.

TABLE I.—*Dosage of Drugs (in Grammes)*

Body Weight (in stones)	Initial Dose (1st 24 hours)	Daily Maintenance Dose for Next Four Days				Total Dose for Course
		1st	2nd	3rd	4th	
1	3·5	1·0	0·5	0·5	0·5	6·0
2	6·5	1·5	1·5	1·5	1·0	12·0
3	10·0	2·0	2·0	2·0	2·0	18·0
4	13·5	3·0	2·5	2·5	2·5	24·0
5	16·5	3·5	3·5	3·5	3·0	30·0
6	20·0	4·0	4·0	4·0	4·0	36·0
7–12	20·0	6·0	6·0	6·0	6·0	44·0

It will be seen from Table II that the average time taken to obtain bacteriological clearance with S.A.B. was 1.8 days, after an average of 9 days persistently positive. It is submitted that this rapid change from positive to negative, especially in patients with long preliminary-observation periods, may in a significant proportion of cases be attributed to chemotherapy. The second observation period of 14.8-days average may be too short to eliminate every intermittent carrier, but to do this thoroughly repeated examination over a much longer period would be necessary. This is not practicable in hospital routine. There was very little difference in the time required to obtain bacteriological clearance in the various age groups.

TABLE II.—*Time Required to Clear Bact. sonnei from Faeces and Rectal Swabs (155 Patients)*

Drug	Age Group	Cases	1st Observation Period in Days			Total Drug (g.)	Days to Clear Bact. sonnei	2nd Observation Period in Days		
			Longest	Shortest	Average			Longest	Shortest	Average
S.A.B. Full dosage	0–5	30	34	2	10·0	10·6	1·7	58	6	15·8
	5–12	3	9	4	5·6	20·6	2·0	16	8	12·3
	Over 12	5	8	4	5·4	37·7	2·0	15	6	11·0
	All ages	38	34	2	9·0	15·0	1·8	58	6	14·8

TABLE III.—*Blood and Urine Concentrations (mg. per 100 c.cm.)*

		Free			Acetylated			Total		
		Highest	Lowest	Average	Highest	Lowest	Average	Highest	Lowest	Average
Blood	S.A.B. 38 cases	8·0	0·5	3·0	1·5	0·25	0·66	8·0	0·5	3·66
	S.A.A.B. Full dose. 17 cases	2·0	0	1·23	0·5	0	0·38	2·5	0	1·60
	S.A.A.B. Half dose. 25 cases	2·25	0	1·16	0·5	0	0·40	2·75	0	1·56
	S.S. 14 cases	0·75	0	0·42	0·25	0	0·17	1·0	0	0·58
	S.A.G. 5 cases	1·25	0·5	0·70	0·5	0·25	0·40	1·75	0·75	1·10
Urine	S.A.B.	270	40	125	150	5	51	320	52	130
	S.A.A.B. Full dose	500	30	193	100	10	48	560	40	241
	S.A.A.B. Half dose	380	12	97·2	120	5	22·2	460	24	119·4
	S.S.	40	7	14·6	10	3·5	6·2	45	14	20·8
	S.A.G.	200	70	148	60	20	38	260	110	186

Using full doses of S.A.A.B. in 71 cases, the average time of clearance was 3.6 days, after an average of 4 days persistently positive. This clearance time is twice that needed with S.A.B., but it must be remembered that in this and the remaining two series culturing on alternate days only may have unfairly lengthened the apparent clearance time. As S.A.A.B. is absorbed less rapidly than S.A.B. and the concentration of drug in the intestine is therefore higher, it was thought that smaller doses of S.A.A.B. might be equally effective. A series of 30 cases was accordingly treated with half the original dose. The results were interesting in that both the time to obtain bacteriological clearance and the number of relapses to positive were less. The S.S. series, treated with full doses, gave a clearance time of 2.4 days, but the relapse rate was the highest of all.

Intermittency of Excretion or Reinfection

Bacteriological relapses—i.e., the reappearance of the Sonne bacillus in faeces or rectal swab after two or more consecutive negative results—occurred in 24 instances. These cases, which are not included in Table II, arose in all age groups, being relatively greatest in the 1–2 and 2–3 years groups, which contained 7 and 5 respectively. Distribution among the various series was as follows: In the S.A.B. series, 3 out of 41 cases (7.3%); in the S.A.A.B. full-dose group, 11 out of 82 (13.4%), and, in the half-dose group, 1 out of 30 (3.3%); while the S.S. group produced 9 out of 26 (34.6%).

Of the 3 cases occurring in the S.A.B. series two became negative after a second course of S.A.B., while the third cleared without further drug. Of the 11 full-dosage S.A.A.B. relapses 8 cleared after a second course, 1 after a third, and 2 without more treatment. The single half-dose S.A.A.B. relapse failed to clear after a second half-dose course, but did so after a further full-dose course. The S.S. relapses cleared as follows: 2 after a second course of S.S.; 2 after a second course of S.S. plus one course of S.A.A.B.; 3 after a course of S.A.A.B.; and 2 without further treatment.

These relapses, when they occurred within a period of a week from the time when the first negative was obtained, are most probably to be attributed to intermittency of excretion, and the majority of our cases fell into this group. But in 4 patients there were 4, 8, 14, and 6 consecutive negative cultures over periods ranging from 2 to 5 weeks, and in these cases reinfection would seem to be a more likely explanation for the reappearance of the Sonne bacillus in the faeces. Sonne dysentery is among the most infectious of diseases, and with the present difficulties with nursing staff it is not always possible to be certain that the high standard necessary in a barrier ward is being maintained. It is important to remember that after an attack of Sonne dysentery constipation may be a troublesome feature, and one or two negative findings immediately after cessation of chemotherapy may be attributable to constipated stools.

Absorption and Excretion

To obtain some idea of the absorption and excretion of the drugs in man the blood concentrations were estimated at the end of the course of drug administration. For the purpose of comparison similar investigations were carried out in five patients who received similar dosages of sulphanilylguanidine (S.A.G.). The results are shown in Table III, from which it will be seen that the concentration of S.A.B. is roughly four times that of S.A.G. and that 20% of this is acetylated, as compared with 34% of S.A.G. With full dosage of S.A.A.B. the concentration is about 30% more than that of S.A.G., and 24% is acetylated. Blood concentration with the half dose is almost as high as with the full. S.S. in full doses gave only one-half the concentration of S.A.G., and of this 29.3% was acetylated.

In addition to the blood estimations a differential white cell count was carried out before, during, and after treatment in the earlier part of each series; but as no significant changes were observed this practice was later abandoned.

The drugs are rapidly excreted in the urine, specimens of which were examined for free and acetylated drug at the same times as the blood estimations. These figures are given in Table III, together with comparative values for S.A.G. In a few cases urine was again tested for presence of S.A.B. and S.A.A.B. 24 hours after cessation of treatment, and was found to contain none with the former and only about 25 mg. (total) per 100 c.cm. with the latter drug. This had disappeared after a further 24 hours.

Toxic Symptoms.—Apart from slight anorexia in adults, especially at the beginning of treatment, possibly due to the large initial dose, none were observed.

Discussion

Although the rapid arrest of the diarrhoea and clearance of *Bact. sonnei* from the stools and rectal swabs of this series of cases, some of which had been persistently positive for a month or more, are striking, the occurrence of 24 cases in which there was bacteriological relapse is disappointing. Intermittency of excretion is obviously a troublesome problem for the hospital administrator who has to decide how many successive negative cultures are necessary before the patient can be considered free of infection.

Working with sulphapyridine in smaller doses than those employed in this series, one of us (Swyer, 1943) found that in a series of 57 cases no bacteriological relapses occurred after 3 days of the negative state, but among 35 controls 6 such relapses developed at periods ranging from 7 to 36 days after apparent clearance. Yannet and his colleagues (1942), on the other hand, reported that in an outbreak of 44 cases of Sonne dysentery in an institution, of which 27 were treated with sulphathiazole, the time needed to obtain bacteriological clearance was actually longer in the drug-treated cases than in controls. Although in the chemotherapy of intestinal infections in which the infecting organism is not found in the blood stream preference is given to drugs of a low degree of absorption, it is worthy of note that in the three series recorded here and the sulphapyridine series quoted above, the efficacy of the drug, particularly in clearing up carriers, was in direct proportion to the degree of absorption of drug from the intestine.

Summary

In the above series 179 patients suffering from bacteriologically proved Sonne dysentery have been treated with sulphanilylbenzamide, sulphanilylamidobenzamide, or succinyl sulphathiazole in doses governed by the patients' weight. The stools became formed, normal in colour, and free from blood or mucus in 24 to 48 hours in the S.A.B. series, and in 38 of these cases bacteriological clearance was obtained in an average of 1.8 days. Improvement in characteristics of stools was marked with S.A.A.B., but rather less so than with S.A.B. The average time for clearance was 3.6 and 2.5 days with full- and half-dosage respectively. With S.S. there was not a great improvement in stools, but clearance time was 2.4 days. Bacteriological relapse rates were: with S.A.B., 7.3%; S.A.A.B., full dose 15%, and half dose 3.3%; S.S., 34.6%.

We have to thank Messrs. Burroughs Wellcome for supplies of S.A.B. and S.A.A.B., and Dr. Prescott and his colleagues of the Wellcome Research Institution for information regarding the chemistry of and animal experiments with the drugs; Dr. R. Cruickshank and staff in the North-Western Group Laboratory, L.C.C.; and Mr. L. G. C. Maslen of the North-Eastern Hospital Laboratory for carrying out the large number of bacteriological, haematological, and biochemical investigations involved in this work. We are also grateful to members of the nursing staff for willing co-operation and help.

HAEMOLYTIC DISEASE OF THE NEWBORN IN ONE OF DIZYGOTIC TWINS

BY

F. STRATTON, M.D., D.P.H.
Regional Transfusion Service, Manchester

F. A. LANGLEY, M.Sc., M.B.
Department of Pathology, University of Manchester

AND

U. LISTER, M.B.
Crumpsall Hospital, Manchester

The occurrence of haemolytic disease in both children of twins is well known (Snyder and Ford, 1941; Buhler, Seely, and McCormick, 1942), but the occurrence of the disease in one of the twins, the other being normal, is less well known. Macklin (1939) collected six such cases from the literature, but in three instances it seemed likely that both children were affected.

The aetiological connexion between the Rh factor and haemolytic disease, and the iso-immunization theory developed by Levine, Burnham, Katzin, and Vogel (1941) to explain this association, supersede the earlier theories of Macklin (1939) and Darrow (1938). Since this theory was formulated, twins affected with haemolytic disease have been described by Buhler, Seely, and McCormick (1942); the children were Rh-positive, as was the father, the mother was Rh-negative, and her serum contained Rh antibodies. Langley and Stratton (1944) reported a case in which an Rh-negative mother gave birth to twins, both affected and both Rh-positive. The maternal serum contained strong Rh agglutinins. Since then those authors have studied two further cases of twin pregnancy in which both children were affected. In each instance the maternal blood was Rh-negative and contained Rh iso-agglutinins, while all the children were of genotype Rh_1rh.

Kariher (1943) reported a case of binovular twins whose mother was Rh-negative, her serum containing Rh antibodies; and while the unaffected child was Rh-negative, the affected child was Rh-positive, the diagnosis being made clinically and confirmed at necropsy. Potter (1944) has reported a double-ovum pregnancy in which one infant was normal but the other died of erythroblastosis on the second day of life. The maternal blood contained no anti-Rh agglutinins, but was Rh-negative; the living child was Rh-negative and the dead one Rh-positive.

The following case is described because it was studied clinically, pathologically, and serologically; moreover, it is of interest, as although only one child was affected both were Rh-positive.

Case Report

Mrs. X., aged 28, was delivered five years ago of an infant which has been completely normal; there was no history of abortions. When first seen in June, 1944, she was found to have a twin pregnancy, the estimated date of delivery being Aug. 20. Her general condition was satisfactory. Four weeks before the expected date she was delivered in hospital, after a normal labour, of a female child weighing 3 lb. 10 oz. and a male child weighing 4 lb.

Both children cried immediately and were vigorous. There were two placentae with separate amniotic sacs. Within six hours of birth the male child showed jaundice of a canary-yellow colour; 12 hours later this had increased in intensity. Twenty-eight hours after delivery the haemoglobin was 70% and the red cells 3,120,000 per c.mm. Vitamin K (5 mg.) was given intramuscularly. An attempt to give a blood transfusion was a failure. On the third day his haemoglobin was 42% and the red cells 1,850,000 per c.mm.

A further attempt at blood transfusion into the tibial bone marrow was unsuccessful, and the child died on the fourth day.

The female twin gained weight steadily, never showed any jaundice, pallor, or other abnormality, and on the fifth day haematological examination showed: haemoglobin 100%, red cells 5,000,000 per c.mm. When 6 weeks old she weighed 5 lb. 8 oz. A blood count showed haemoglobin 70% and red cells 4,000,000 per c.mm.

Pathology.—The relevant post-mortem findings were as follows: Naked-eye:—The skin and mucous membranes were deeply jaundiced (bright yellow). Blotchy haemorrhages were present in the lung, and there were a few small haemorrhages on the peritoneal surface of the gut. Bile was present in the intestine. The liver was enlarged and deeply jaundiced; the bile ducts were normal. The spleen was enlarged and firm. The brain was pale. The other organs showed no abnormality, except bile-staining.

Microscopic:—Many of the liver cells were vacuolated as by fat, and about half the remainder showed the clear watery appearance of glycogen infiltration. The reticulum framework was normal. There was widespread haemosiderosis. Bile thrombi were present in the intercellular canaliculi. Fairly numerous foci of haemopoiesis were found outside the sinusoids. These were mostly erythropoietic, though there were a few myelocytes. Primitive blood cells were also present in the sinusoids. There was marked leucopoiesis in the portal tracts, but there were also some erythropoietic foci. The general architecture of the spleen was normal. There was a fairly intense leucopoiesis, but only scanty erythropoiesis. The kidney showed subcapsular glomeruli incompletely developed; no haemopoiesis. The blood in the vessels of the liver and kidney contained many nucleated red cells.

Serology.—The Wassermann reaction in the mother was negative. The results of examination of the erythrocytes of children and mother were as follows:

	α	β	α_1	Anti-Rh	Anti-Rh_1	Anti-Rh_2	St	
Mother ..	+	−	+	−	−	−	+	A_1 Rh-neg.
1st child ..	+	−	+	+	+	−	+	A_1 Rh_1rh
Twins A (♂)	−	−	−	+	+	−	+	O Rh_1rh
Twins B (♀)	−	−	−	−	−	+	+	O Rh″rh

The maternal serum contained a weakly active Rh antibody when first tested on the second day after delivery. When retested a month after delivery the Rh agglutinins were much stronger, and titration at 37° C. gave the following results:

Cells	Rh_1Rh_2	Rh_1rh	Rh_2rh	Rh_1Rh_1	Rh′rh	Rh″rh	Rh-neg.
Titre	64	32	16	64	4	0	0

Comment

The male twin was considered to be affected with haemolytic disease, the diagnosis being based on the clinical, haematological, and pathological data. The picture was that of a jaundiced newborn second child with a progressively severe anaemia in the absence of syphilis, sepsis, or haemorrhage, resulting in the death of the child. In the haematological data the normoblast count was unfortunately not recorded, but at necropsy the liver and kidney blood vessels contained many nucleated red cells. Prematurity, confirmed by the incomplete glomerular development and hepatic glycogen infiltration, rendered the interpretation of the histological appearances difficult. Haemopoiesis was, however, rather more intense than is usual with this degree of prematurity, and there were marked splenic leucopoiesis and excessive portal erythropoiesis. All the above findings are consonant with a diagnosis of haemolytic disease of the newborn.

The female child is considered to be healthy and unaffected by the haemolytic disease. Any suggestion that the above might be a mild case is negatived by the clinical and haematological findings.

The blood group Rh has been shown (Wiener, Sonn, and Belkin, 1944; Race, Taylor, Boorman, and Dodd, 1943; Race, Taylor, Cappell, and McFarlane, 1944) to consist of many subtypes, or, more correctly, the Rh gene is an example of multiple allelomorphism. In differentiating the types of Rh certain human sera are used. In this family the mother is Rh-negative (rhrh), while the affected child was of genotype Rh_1rh; the unaffected one is Rh″rh. It seems that the father is therefore Rh_1Rh″.

The maternal Rh antibodies are of the type anti-Rh′, and showed a considerable rise in titre during the first few weeks after birth of the child. It will be seen that while they react strongly with cells of a genotype similar to that of the affected child, they completely failed to react with erythrocytes of a genotype like those of the unaffected infant.

In previous cases described (Potter, 1944; Kariher, 1943) the unaffected child has been of the same group as the mother—that is, Rh-negative—and therefore quite incapable of reacting with Rh antibodies in the maternal serum. In this case, however, the child is Rh-positive, and it seems that the mother has failed to respond adequately to this stimulus—hence a normal child.

These observations afford substantial confirmation of the theory of Levine *et al.* (1941) that iso-immunization of the mother by "dominant hereditary blood factors" seems necessary for the child to be affected.

Summary

A case of haemolytic disease of the newborn is described in one of dizygotic twins, both being Rh-positive but of different genotypes.

The affected child became jaundiced within six hours of birth and died four days later, post-mortem findings confirming the diagnosis.

The Rh agglutinins detected in the maternal blood correspond to sensitization by the affected child, thus confirming the iso-immunization theory.

Our thanks are due to Prof. S. L. Baker, Dr. Ramsey, and Dr. J. F. Wilkinson for permission to publish this case. We are indebted to Dr. G. L. Taylor for a supply of St serum.

Medical Memoranda

Impetigo treated with Sodium Penicillin Cream

In view of the present overcrowding in Service conditions the following case record may be of some interest.

On July 12, 1944, a rating complained of a rash on his face which was irritable, wet, and spreading. This on examination showed typical raised yellow crusts and was diagnosed as impetigo. Treatment was started by de-scabbing with warm eusol, thoroughly drying, and applying twice daily a paint consisting of acriflavine 1/2 gr., tannic acid 20 g., and water to 1 oz.

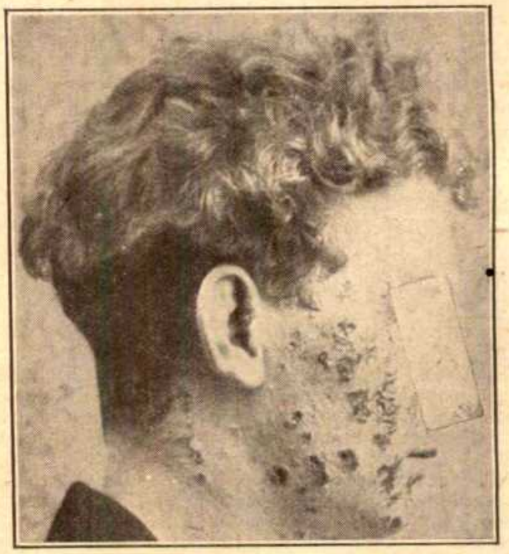

FIG. 1

In spite of treatment the condition continued to spread, and ung. hydrarg. ammon. dil. was tried without effect. On July 21 the patient was admitted to sick quarters, when Fig. 1 was taken.

Treatment with sodium penicillin cream was now begun. This consisted of equal parts of lanolin, cod-liver oil, and water, to which was added enough sodium penicillin to make a cream of 500 Oxford units per gramme. The cream was applied thinly twice daily after de-scabbing with warm eusol. The treatment was repeated for three days. On the second day of treatment there was a vast improvement, with at least 50% reduction of the lesions, the remaining areas being dry and showing signs of healing. On the third day of treatment all the smaller spots were healed and the larger ones were 25% of their original size. The spots on the pinnae were much slower in healing than those on the cheeks or neck. On the fourth day (July 24) all areas except the lower part of the right ear were healed. Two days after this the spot on the ear showed no change. Treatment was altered to ung. hydrarg. ammon. dil., and this spot cleared on July 31—i.e., 10 days after penicillin treatment had been started.

A Gram-stained smear of the lesions before sodium penicillin treatment showed a mixed infection of streptococci and staphylococci, also a few Gram-negative cocci and bacilli—type not recognized.

In all, 10 g. of cream was used, each gramme containing 500 Oxford units: total local dosage, 5,000 Oxford units. No parenteral treatment was given. This cream has also been employed with equal success on septic burn cases. As a face cream it is too soft, tending to run downwards.

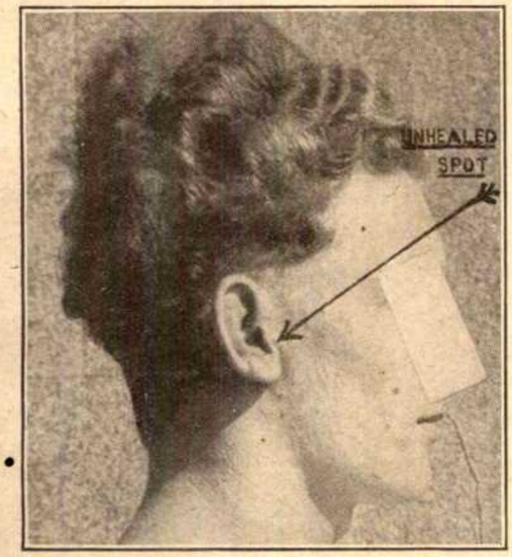

FIG. 2

The photographs show the patient before sodium penicillin treatment was begun and four days later, when all areas had healed except a small spot on the lower part of the right ear.

Carcinomatosis simulating Appendicitis

The following unusual case may be found to be of clinical interest.

A patient aged 50, suffering from cardiac disease, developed symptoms of appendicitis. Generalized central abdominal pain settled down in a tender right iliac fossa, with vomiting, rise of temperature, and slight leucocytosis. There was no history of rheumatism or of syphilis, and the Kahn blood and C.S.F. tests were negative. While further investigation was in progress a cardiac attack suddenly proved fatal, and a post-mortem examination revealed inflammation of the appendix due to invasion by secondary carcinoma. Both the internal and the external appendicular structures contained growths, while an intracaecal mass obstructed the appendix orifice. The coronary arteries were in bad condition, with thrombotic obstruction of the first part of the left. There was generalized arteriosclerosis.

Microscopical examination revealed inflammation and invasion by columnar-celled tubular carcinoma which was secondary to a recto-sigmoid carcinoma of small dimensions but showing unusually early spread. Blood-stained fluid was present in the peritoneal cavity and there were a few peritoneal metastatic implants.

Before the "appendicular" attack there had been no signs or symptoms of any intra-abdominal pathology. This is a type of case which serves to warn that a light-hearted prognosis given before an intra-abdominal operation can sometimes be rudely shattered.

I am indebted to Dr. R. Ström-Olsen, physician-superintendent of the hospital, for permission to publish this case.

Reviews

TREATMENT OF SYPHILIS

The Modern Treatment of Syphilis. By Joseph Earle Moore, M.D., with the collaboration of Jarold E. Kemp, M.D., Harry Eagle, M.D., Paul Padget, M.D., Mary Stewart Goodwin, M.D., and Frank W. Reynolds, M.D. Second edition, third printing. (Pp. 717; illustrated. 38s. 6d.) London: Baillière, Tindall and Cox. 1944.

The second edition of *The Modern Treatment of Syphilis* by Joseph Earle Moore appeared in 1941, and was reviewed in these columns on Aug. 1, 1942; a second printing was carried out in May, 1943, when the chapter on intensive arsenotherapy of early syphilis was completely rewritten and a chapter on venereal disease control in the U.S. Army and Navy included, largely contributed by Frank W. Reynolds, whose name has been added to the list of collaborators; a third printing was carried out in March, 1944, and this is now available.

The section on intensive therapy has been enlarged from 7 pages to 18, and the bibliography much extended. This form of treatment has many advocates and appears to give a high rate of cure; nevertheless, the mortality from treatment, as shown in Table 126, would seem to preclude its routine use, since daily injections of mapharside over a period of 3 weeks give an estimated fatality rate of 1 in 400. Incidentally, the method recently employed in the U.S. Forces in this country, whereby daily injections of mapharside, plus a few injections of bismuth, are given over a period of 20 days, has been remarkably free from fatalities, due, no doubt, in part at least to the fact that patients have all been young and healthy men. It is surprising that no mention is made of penicillin—at least the word is not to be found in the index—for this drug was used by Mahoney in New York as long ago as December, 1943, and is now being employed on a large scale in both the American and British Forces for the treatment of early syphilis. The chapter on V.D. control in the Army and Navy is particularly opportune, and deals with the incidence of these diseases in the armed Forces in peace and war, their control in civil life and their relation to the armed Forces, treatment in the Services, prostitution, prophylaxis, education, punitive measures, and the V.D. control officer in this war. The section devoted to penalties imposed on U.S. Service men contracting V.D. is of special interest; it is generally agreed that such penalties are utterly illogical, do not appreciably reduce the incidence, and do tend to encourage concealment.

This is surely the most compendious and authoritative book in the English language on the treatment of syphilis; but methods are changing so rapidly that much of the contents of such books must be out of date before they reach the reader.

PERSONALITY AND BODILY MAKE-UP

The Physical Basis of Personality. By V. H. Mottram. (Pp. 124. 9d.) Harmondsworth; Penguin Books.

Here is a popular treatise on how much our personality owes to our bodily constitution, written on the whole in simple non-technical language and with that lucidity which is characteristic of the author. Bodily constitution must depend on hereditary endowments; and the cell, with its nucleus, its chromosomes, and its genes, is described. The ballet of the chromosomes and their illumination of the Mendelian theories of inheritance are vividly depicted, and attention is drawn to the advances made in mapping the chromosomes and the identification of the location upon them of unit factors in inheritance at least in the fruit fly. Mendelian transmission in man is illustrated by colour blindness and haemophilia, but it is pointed out that all such characteristics are not clear-cut, and features distinct in the parents may be blurred in the offspring—"one white, one black, and two khaki."

The influence on the personality of variations in the structure and function of the nervous system is pointed out, and Prof. Mottram devotes a long chapter to the effects of over- and under-activity of the endocrine glands, especially the gonads. He is, however, at pains to warn the reader against too easy acceptance of a physical as opposed to a psychic explanation of behaviour. As he says of the pituitary: "The abnormal person may be morose, a bully, disobedient, a liar, and a thief directly because his pituitary is not exerting a due influence, or he may have become so because he feels at a disadvantage in coping with affairs in a world of well-endowed folks and compensates for his inferiority by these unpleasant reactions."

In a final chapter the author deplores the pessimistic material philosophy of the universe to which scientific acceptance of a physical basis of the personality would condemn us. Against this he himself rebels, and points out that the whole scientific structure of knowledge is based on the somewhat slender foundation of our senses. Science explains how but not why the universe works; its laws merely imply that phenomena may be observed as if they obeyed them; the true scientific attitude makes no claim that they do so behave. Prof. Mottram believes that mystical vision denies this true reality and that the "scientific personality" may not be "that quality or assemblage of qualities which makes a person what he is as distinct from other persons" (O.E.D.) but rather a "persona" masking a spark of that transcendental reality experienced by the mystics.

INTRACRANIAL ANEURYSM

Intracranial Arterial Aneurysms. By Walter E. Dandy. (Pp. 147; illustrated $2.50.) New York: Comstock Publishing Company.

This monograph has been based on 108 cases of intracranial aneurysm, accumulated during many years of cranial exploration—some diagnosed, some suspected, and others just discovered. Very detailed data on these cases are contained in tables at the end of the book. The rest is made up of a careful analysis of all aspects of the case material and a synopsis of much of the literature. After describing intracranial aneurysm in general Dr. Dandy devotes a large chapter to the features presented by aneurysms arising from each of the main arteries in turn, and then goes on to a lengthy description of preoperative and operative techniques and results. The two chapters dealing with operative treatment are the most valuable of those written by Dr. Dandy, for they are superbly illustrated by artist's sketches and demonstrate vividly his technical achievements in this field. Dandy does not consider that all congenital aneurysms arise from medial defects at bifurcations, so well demonstrated by Forbus, but thinks that some begin at the point of origin of obliterated tributaries, and he thus explains the appearance of aneurysms distant from an arterial division. He gives an interesting account of some unusual symptoms of aneurysms, especially those which may follow lesion of the third nerve.

The most important section of the book, in which an original contribution to knowledge has been made, is that written by Dorcas Padget on the embryology and anatomy of the circle of Willis. She presents the results of study of the cerebral arterial tree of 17 embryos ranging from 3 to 43 mm., and co-ordinates her own observations on the circle of Willis in adults with those of earlier workers.

Notes on Books

Prof. A. D. GARDNER'S *Bacteriology for Medical Students and Practitioners*, which has appeared in its third edition (Oxford University Press; 8s. 6d.), is a little less slim than its predecessors, but still perhaps of unduly modest size for its purpose. Its clear and simple descriptions, illustrated by line drawings, are admirable of their kind, but some teachers prefer that the student should use a more ambitious and comprehensive textbook. A notable new feature in this edition is a chapter on disinfectants, antiseptics, and bacterial chemotherapy, which embodies conclusions from the author's own original work.

The issue of the *Proceedings of the American Philosophical Society* dated September, 1944 (Vol. **88**, No. 3), is devoted to a symposium on wartime advances in medicine, and also the text of the Penrose Memorial Lecture on "International Labour Organization Lessons for 25 Years," by Mr. Harold B. Butler, Minister from Great Britain at H.M. Embassy, Washington. The subjects of the papers include water requirements of castaways; blood derivatives and blood substitutes; the present status of penicillin in the treatment of infections; advances in the treatment of wounds; human problems in military aviation; immunization; and neuropsychiatry. The publications of the American Philosophical Society are issued from Independence Square, Philadelphia, Pennsylvania.

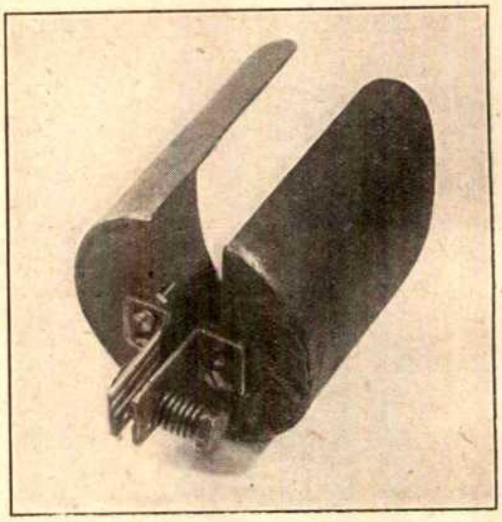
Preparations and Appliances

A PROTECTIVE SCREEN FOR ARC WELDERS

Fl. Lieut. J. NOEL JACKSON, M.B., B.S., writes:

Some of the constructional work in the establishment to which I devote part of my time as factory doctor is carried out by means of spot welding. For this the arc-welding method is used. I was impressed by the somewhat inadequate precautions taken against the radiation emitted by the arcs, and decided that arc workers should be provided with individual booths so that the eyes of other workers were protected from the harmful rays.

The first step to this end was to screen off each individual welder with thin sheet metal, finished with a dull black matt surface. As an additional safeguard I designed and made the hood shown in the accompanying photograph. The result is crude but effective. The hood is clipped on to the welding-rod, which fits into one or other of the grooves shown on the bracket, depending on the thickness of the rod. I found that these two grooves and the employment of a nut and bolt provided all the adjustment necessary for use with the varying thicknesses of arc-welding rods. It should be remembered that the arc-welding rod is burnt away in use and that this hood has to be moved backwards. Although the hood itself becomes quite hot, it can be readily moved by the operator, who wears very thick gloves.



The hood is roughly cylindrical, but the open end is cut off at an angle. After watching many operators, I found that some of them adjust the rod at an angle of about 45° to the surface on which they are working. The rather broad slit along the top of the hood enables the operator to see the point of the rod. This also allows an escape of the rays, but only in an upward direction away from other workers, and backwards in the direction of the operator himself, who is, however, holding a shield, so that the rays do him no harm.

Civilian patients likely to be detained in hospitals and sanatoria for long periods may be given the opportunity to pursue educational courses. The Ministry of Education has informed education authorities that a course of study or craft work can contribute materially to accelerating the recovery of patients, and the Minister believes that the suggestion will be considered by authorities with every sympathy. It would be for the hospital or sanatorium authorities to decide, on the advice of the medical officer in charge of the case, whether a patient should be encouraged to pursue any such course. In suitable cases the patient will be put in touch with the Chief Education Officer for the area. This scheme does not apply to members of H.M. Forces detained in hospital. They are the responsibility of the Service Departments and are covered by the War Office Correspondence Scheme until discharged from the Forces on medical grounds. If they are retained in hospital after such discharge they become civilian patients falling for consideration under this scheme, except that they may complete any particular correspondence course for which they were enrolled under the War Office scheme.

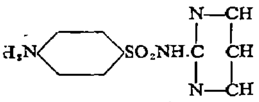
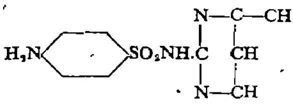
LPHAMERAZINE: A NEW SULPHONAMIDE

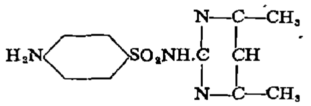
he output of new sulphonamide compounds is less brisk an was the case some years ago, and there is reason to ppose that the antibacterial activity of this series of mpounds will not be significantly increased by future scoveries. Nevertheless, one new compound—sulphaerazine (or sulphamerizine)—has been the subject of uch work in America, and it appears likely to become a luable addition to the clinical armamentarium. Sulphaerazine is 2(*p*-amino-benzene sulphonamido)-4 methyl rimidine, and its relation to sulphadiazine and to sulphamethyl pyrimidine (sulphamethazine or sulphamezathine) shown by the following formulae:



Sulphadiazine



Sulphamerazine



Sulphamezathine

hese three compounds have approximately the same antiacterial activity *in vitro* or in experimental infections of ice, but their pharmacological properties vary somewhat; e choice between them depends chiefly on differences in osorption, blood concentration, and excretion.[1]

Sulphamerazine is more quickly absorbed than sulphaiazine and more slowly excreted than sulphamezathine, that its concentration in the blood rises more quickly d is sustained longer than in the other two compounds. dose of 3.5 g. to a 150-lb. man by mouth produces an verage blood concentration of 8 mg. per 100 c.cm. in hours, and 10 mg. in 4 hours; a level greater than 6 mg. maintained for 24 hours, and one greater than 3.5 mg. r 48 hours. An effective blood level is reached more uickly with sulphamerazine than with sulphadiazine, and ere is less need in acutely ill patients to start the treatt with an intravenous injection of the sodium salt in rder to avoid delay while the compound is being absorbed om the intestine. Since sulphamerazine is retained in the ody to a greater extent than sulphadiazine it is rather ore toxic, dose for dose; but when the higher blood oncentration is taken into account there is no significant ifference between them. An average blood concentration f 27 mg. per 100 c.cm. can be tolerated by monkeys for ng periods (provided that sufficient fluid is given to preent renal blockage); but one of 32 mg. per 100 c.cm. is toxic, causing damage to the kidneys, depression of the activity of the bone marrow, and possibly degeneration of the liver. However, these blood concentrations are much higher than what is needed for clinical purposes, and in actual practice these toxic effects are not to be expected. In particular, the occurrence of peripheral neuritis or damage to the nervous system should be extremely rare, or completely unknown, judging by animal experiments; sulphamerazine is less damaging to the nervous system of the chick than either sulphadiazine or sulphathiazole. In man 9% to 15% of the drug in the body is in the conjugated form, and so is 37% to 50% of the drug in the urine. Urinary excretion accounts for 40% (average) of the drug after 24 hours, and for 58% after 48 hours, following a single dose of 3 g. by mouth; the final total recovery is 84% to 100%. The concentration in the cerebrospinal fluid is about 0.3 to 0.7 of that in the serum. The ratio between the concentration in the serum and that in the red blood corpuscles varies greatly, but averages about 3 to 1, and the concentration in the whole blood is about three-quarters of that in the serum.[2 3] The toxic symptoms caused in man are much the same as those caused by sulphadiazine.[4]

As stated above, the toxicity of sulphamerazine for the body as a whole in animals is about the same as that of the other two compounds when measured in terms of equal blood concentrations. The toxicity for the kidneys, however, varies widely in the different cases. In animals sulphamezathine never damages the kidney, no matter what the blood concentration may be. Sulphamerazine may cause damage after high doses, owing to blockage of the urinary passages by crystals of the drug or of its acetyl derivative, but it is much less toxic in this respect than in sulphadiazine. These differences in respect of the kidney seem to depend upon the different solubilities of the compounds. In acid urine sulphadiazine is the least soluble of the three and sulphamezathine the most soluble: thus at *p*H 6.0 (acid) the solubility of sulphadiazine is 17 mg. per 100 c.cm., of sulphamerazine 38 mg., and of sulphamezathine 69 mg., while the solubilities of their acetyl derivatives are respectively 30 mg., 39 mg., and 67 mg. per 100 c.cm. However, if the urine is made neutral or slightly alkaline the solubilities of all the compounds are much increased, and the differences between them are much less. Thus at *p*H 7.6 (faintly alkaline) the solubility of sulphadiazine is 139 mg. per 100 c.cm., of sulphamerazine 158 mg., and of sulphamezathine 144 mg., while the solubility of the acetyl derivatives ranges from 176 to 210 mg. per 100 c.cm. Accordingly it is found in animal experiments that, if the urine is kept alkaline by giving alkalis by mouth, none of the three compounds has injurious effects upon the kidney.[1] Though it is not possible to do analogous tests on man, the clinical experience is in general agreement with these experimental results. Sulphadiazine, as is well known, is apt to lead to blockage of the urinary passages, but if the urine is kept alkaline very large doses can be given with impunity. Sulphamerazine has caused renal symptoms in 6 out of about 400 reported cases. Sulphamezathine seems very rarely to cause urinary lesions, although one case of transitory urinary suppression and one of haematuria occurred among 77 patients treated by Peters and Easby.[4] The other toxic symptoms caused by sulphamerazine in man are much the same as those caused by sulphadiazine.[5]

[3] Goodwin, R. A., jun., Peterson, O. L., and Finland, M., *Proc. Soc. exp. Biol.*, N.Y., 1942, **51**, 262.

[4] Peters, B. A., and Easby, M. L., *British Medical Journal*, 1943, **2**, 230.

The dosage recommended for sulphamerazine (e.g., in lobar pneumonia in adults) is an initial dose of 3 to 4 g., followed by 1 g. every 6 hours until the temperature remains normal for 48 hours; then the dose is reduced to 0.5 to 1 g. every 8 hours and the drug is discontinued on the fifth to eighth day. According to the clinical experience reported so far sulphamerazine is therapeutically very similar to sulphadiazine. Thus Gefter and his colleagues[6] treated 45 patients with meningococcal infections, giving on the average 56 g. in 9½ days; their mortality rate was 6.7%; in a previous series treated with sulphadiazine their mortality rate had been 12.5%. Lepper, Sweet, and Dowling[7] treated 22 cases of meningococcal meningitis with sulphamerazine and 22 alternate cases with sulphadiazine; in each series the mortality rate was 9.1%. Flippin and his co-workers[8] treated 80 cases of lobar pneumonia with sulphamerazine and 80 alternate cases with sulphadiazine. Apart from a slightly quicker defervescence among the patients treated with sulphamerazine the clinical results of the two treatments were practically indistinguishable as regards both therapeutic efficiency and freedom from toxic reactions. Six of the patients on sulphamerazine and eight of those on sulphadiazine died. Experience gained during the treatment with sulphamerazine of 116 cases of miscellaneous infections has also been reported by Hall and Spink[9]; they found its therapeutic activity and toxicity to be similar to those of sulphadiazine, a lower dosage being required to produce the same result. It was less toxic than sulphanilamide, sulphapyridine, or sulphathiazole, but sulphathiazole appeared to be more effective in the treatment of staphylococcal infections. Similar experiences have been reported by Hageman, Harford, Sobin, and Ahrens.[10] Anderson, Oliver, and Keefer[11] found that sulphamerazine was as effective as sulphadiazine and that the total dose required was only one-third to one-half as great.

Altogether it may be concluded that sulphamerazine is closely similar to sulphadiazine in its toxicity and therapeutic effectiveness, and that its chief advantage is the lower and less frequent dosage needed for its use; this feature seems to have recommended it strongly in the Australian Armed Forces, no doubt because less frequent administration represents a great saving of the labour of the nursing staff. The compound is not yet available in this country for general clinical use, and presumably it may remain unobtainable until the end of the war. But when supplies do come to hand sulphamerazine is a compound which will deserve careful clinical trial. Provided that the price is not too high it might well prove to the most desirable sulphonamide compound for gene medical use.

SURGICAL TREATMENT OF INTRACEREBRA HAEMORRHAGE

Elsewhere in this issue Rowbotham and Ogilvie report tw cases in which a large intracerebral collection of bloo was successfully aspirated and the patients, who had be hemiplegic, made a full recovery. In both the presum cause of the bleeding was rupture of a congenital intr cranial aneurysm. It is important that both patients we young, for a congenital defect in the tunica media is n the only cause of intracranial aneurysms. The authors well to discount syphilis as a cause of these aneurysms and they are not alone in this—but there will be few w agree with them that they are not caused by any oth degenerative process, for some authorities consider th arteriosclerosis is the most common cause of intracran aneurysms,[1] while mycotic aneurysms accounted for int cranial haemorrhage in 5 out of 120 cases described Dandy.[2] Dandy has recently questioned Forbus's[3] conte tion that all congenital aneurysms arise at the bifurcati of vessels, for he considers that some arise along the leng of a vessel at the point of origin of an obliterated and v tigial offshoot of the parent trunk. This conception wou explain the appearance of some aneurysmal sacs at a sh distance from a bifurcation of the branches of the cir of Willis.

This emphasis on the exact cause and site of intracran aneurysms has practical importance as well as theoreti interest, for although aspiration of an intracerebral haem toma may remove the immediate danger to life and relie many of the symptoms which it has produced, the su geon's main concern should be to eradicate the cause the bleeding. This is a much more difficult undertaki than removal of the extravasated blood. In his rece monograph Dandy[2] has described the results of operati treatment of the aneurysms themselves. It has for ma years been recognized that the patient is more likely survive if, as in the present two cases, the aneurysm ru tures into the cerebral substance, for the resistance this tends to limit the amount of bleeding. After t catastrophe a state of equilibrium between the pressu in the aneurysm and its surroundings is established, if t patient is fortunate. With the high intracranial pressu which has developed as a result of the mass of blood cl papilloedema slowly appears and increases in degree, b the delay in the papilloedema does not necessarily indica a delayed rise in intracranial pressure. When the state equilibrium is reached it is a comparatively simple matt to aspirate the intracerebral haematoma, but Dandy urg that after this an attempt should be made whenever po sible upon the aneurysm itself. In the past six years has operated upon 36 of these cases and has succeeded finding and dealing with the aneurysm in 30 of them.

[1] Strauss, I., Globus, J. H., and Ginsburg, S. W. (1932). *Arch. Neurol. Psych* Chicago, 1932, **27**, 1080.
[2] *Intracranial Arterial Aneurysms*, 1944, Ithica, New York.
[3] *Johns Hopk. Hosp. Bull.*, 1930, **47**, 239.

s claimed a cure in 20 of these (70%), but 9 of his 36 tients have died. These results are laudable, for they ould be judged against the technical difficulties which e encountered in this field of neurosurgery. Dandy takes e view that the aneurysm must be isolated from the circle Willis, and does not advise ligation of the internal carotid tery alone, whether the aneurysm is above or below the inoids. His reasons for this are that the results are both certain and disappointing. When the aneurysm is below e clinoids the affected vessel should be clipped distal to e aneurysm and the internal carotid artery ligated in the ck. Matas's[4] test—trial occlusion of the artery in the ck for 10 minutes—should always be carried out before is course is adopted. When the aneurysm is localized tracranially and is accessible to intracranial operation e of many different methods of ablation, each of which pends upon the situation and type of aneurysm, may be opted. These involve tying or clipping on each side of e aneurysm, coagulating it, or actually removing it cometely. McConnell[5] successfully introduced a portion of uscle into the sac and secured complete thrombosis of e aneurysm, while Dott[6] applied muscle to the hole in e sac and so cured the bleeding without disturbing the eurysm. Dandy advises electrocoagulation as well as troduction of muscle in order to increase the speed of agulation.

It is not many years since Symonds[7] paved the way to the rrect diagnosis and location of intracranial aneurysms, d now the surgical cure in suitable cases is an estabhed fact. Unexplained intracranial haemorrhage in ung patients does not now necessarily carry a gloomy ognosis or prospects of an invalid existence. Even so, effect a very slight improvement in the mortality from ese aneurysms requires great skill, for it is hard to say nich is the most difficult—to locate the site of the causal eurysm or to render it harmless after it has been cognized.

NEURONE AND MIND

a stimulating address to the Royal Society of Edinrgh[8] Prof. R. J. A. Berry has expounded the general esis that the neurone is the organ of the mind, and—no urone, no mind. Prof. Berry sets out to show this by king such simple measurements as the size and weight of e post-mortem brain. Between birth and the age of 6 the ain approximately quintuples in size and weight; between th and maturity it adds to its weight by roughly 1,000 ammes. Most, though not all, of this increment is due the myelinization of the cerebral axones of the white edullary centre. When the mentally defective are comred with the normal the mean weight of the defective ains becomes smaller and smaller as more and more vere degrees of defect are studied. Within the range of normal there is enormous variation. As a group the gest brains were shown by university teachers; the allest averages within normal range were shown by the iftless and thriftless, criminals, and reformatory boys. ze and weight, though closely related to intellectual velopment, can be imperfect guides. Some defectives can have heavy brains, the abundant weight being due to an excess of glial tissue.

It has been estimated that the normal healthy brain contains about 14,000 million cells. The possible number, variety, and complexity of neuronic arcs that could be developed on such a structural basis are sufficient to explain the whole range of human behaviour. But how can one conceive of this immensely complicated organ operating in its functions of memory, deliberation, and action? If we think of the primitive nervous system being developed out of the reflex arc an essential part in attaining a greater complexity of behaviour is played by the interposition of a great array of cells between the receptor and effector parts of the arc, with a resulting temporal delay. These intervening cells are involved in actions of many kinds and over many years, so that the experiences of the past can be expected to have an influence on the behaviour of the present. Different workers have different ideas of how this happens. Herrick has spoken of "a complex web of interrelated associational cortical neurones, technically known as an 'engram.' Once these cells have been activated they remain charged with a potential energy. When reactivated in recall the reserve energy of these engrams is released . . . and we have thoughts of previous stimuli —that is, memory of past events." Importance is attached not only to the mere existence of engrams but also to the proper order and sequence of their activation.

Prof. Berry illustrates the practical use of such a theory to explain the phenomena of dreams. In sleep there is a temporary inactivity of certain of the most recently evolved cells of the neo-cortex. Engrams become incomplete; there is no barrier to stop the energy of still active cells of other engrams overflowing into arcs to which they do not belong. The result is a commingling of distorted bits of recent and remote memories, with the fantastic effects which we all know. Berry considers that this neuronic theory of cerebration excludes the possibilities which have been mooted in different quarters, of dreams of the future and of thought transference. However this may be, it provides a schema of great potential usefulness for the understanding of such various observations as drug effects, effects of local brain lesion, and Pavlovian conditioning. It will by some be regarded as an over-simplification; but simple theories are always to be preferred when it is only simple facts that are known with precision.

INTESTINAL ANTISEPTICS

Intestinal infections are usually divided into two categories: typhoid and paratyphoid, in which the local intestinal lesions are accompanied by systemic invasion; and dysentery, cholera, and the bacterial food-poisonings, where the infection is confined to the gut. So far no drug of the sulphonamide series has proved effective in shortening the chemical course of enteric infections, although amelioration of the toxaemia has been claimed. The failure to cure or to eliminate the infecting organism may be attributed partly to the pathology of typhoid, which makes the organism in the lymphoid tissue and in the gall-bladder rather inaccessible to attack, and partly to the natural resistance of the typhoid–salmonella family to the bacteriostatic action of the sulphonamides. Thus salmonella gastro-enteritis, although a self-limited and localized disease of one or two days' duration, is frequently followed by a convalescent carrier state which is quite unsusceptible to sulphonamide therapy. Therefore the search for new drugs that may prove effective against this group of intestinal pathogens still goes on. Unfortunately it is not possible with these organisms to reproduce in animals a

e syndrome similar to the natural infection in man, and the experimentalist has to rely on test-tube results in assessing the value of new preparations against the intestinal pathogens. In this way Schweinburg and Yetwin[1] have tested a number of new sulphonamides prepared from drugs of known potency—sulphamerazine, sulphadiazine, and sulphathiazole—by the addition of a phthalyl radicle. Their results showed that *in vitro* sulphamerazine and phthalyl sulphadiazine were more effective than sulphadiazine against the dysentery organisms but less so against the typhoid-paratyphoid bacteria. The addition of the phthalyl radicle to sulphamerazine decreased its activity against all intestinal pathogens, while phthalyl sulphathiazole had no advantages over sulphathiazole itself. The possibility of using enteric-coated tablets of the more active sulphonamides—e.g., sulphathiazole and sulphadiazine—to ensure a local antiseptic action in the lower reaches of the bowel seems to be worthy of more consideration.

In the case of the dysenteries there is now abundant evidence that Flexner infections respond well both clinically and bacteriologically to most sulphonamides, which is in line with the greater susceptibility of the Flexner group of organisms in the test-tube. However, in view of the greater clinical severity with considerable dehydration in Flexner infections, preparations which are not readily absorbed—e.g., sulphaguanidine or succinyl sulphathiazole in doses of 9 to 12 g. daily for 5 to 7 days—are preferable to others which, being absorbed, may have deleterious effects on the kidney. On the other hand, Sonne dysentery, which is the prevalent infection in this country and which, if notifications are reliable, is greatly on the increase, does not respond to sulphaguanidine unless the drug is given early in the infection or in large doses—e.g., 30 g. in the first 2 days followed by 7.5 g. daily. In the cure of the frequent convalescent Sonne carrier succinyl sulphathiazole in doses of 10 g. daily for 5 days has been found effective, but in our present issue Swyer and Yang rank it behind two new drugs—sulphabenzamide and sulphamidobenzamide, which have been found active *in vitro* against both the enteric and dysentery groups of organisms. The absorbability of these new drugs is intermediate between succinyl sulphathiazole and sulphaguanidine and the other common sulphonamides, and in moderate doses given according to weight they have proved remarkably effective in the bacteriological cure of Sonne carriers. Thus, with sulphabenzamide only 3 out of 41 cases (7.3%) and with sulphamidobenzamide 12 out of 112 cases (10.7%) were not cured, or relapsed after the initial course of treatment. A number of the bacteriological "relapses" occurred after 4 or more consecutive negative rectal-swab examinations, and it is difficult to be sure if they were due to reinfection or to intermittency of excretion of the organism. Intermittency of excretion has become rather a bogy for the hospital administrator, who is naturally unwilling to retain a young child in hospital for some weeks after that child is clinically well. The patient with Sonne dysentery admitted to hospital represents only a small fraction of all infected children in the community, and it seems irrational to isolate one child in surroundings which may be prejudicial to its health while the other 99 are free to spread the infection. With Sonne dysentery, a widespread endemic infection, 2 or 3 negative cultures before discharge are probably adequate unless the child is returning to a residential institution or day nursery, when 4 to 6 successive negative examinations may be required. Control of dysentery in a community depends on a high standard of personal hygiene, an appreciation by the practitioner of the frequency of the mild atypical
case and the contact carrier, and the use of an intestin
antiseptic that will ensure bacteriological as well as clinic
cure of the infection.

NEW INTERNATIONAL SANITARY CONVENTION

Drafted and sponsored by U.N.R.R.A., two new Inte
national Sanitary Conventions, amending those at prese
in force, came into operation on Jan. 15. By that da
the signatures of 17 of the Governments of the Unit
Nations were affixed to the new Conventions in Washin
ton. Even before the war it was recognized that advanc
in preventive medicine had rendered the present Conve
tions obsolescent—that governing sea and land traf
dating from 1926, and that on air travel from 1933. Tl
development of vaccination against yellow fever in pa
ticular has required changes in the yellow-fever clauses
the air convention, and the British Interdepartmental Cor
mittee on the Control of Yellow Fever had already recoi
mended drastic alterations in these provisions: the
changes have been adopted in the areas in Africa co
cerned. Moreover, the migrations of large numbers
people expected after the war required special consider
tion, although the health measures needed for the
organized movement have been dealt with by a speci
agreement between the Governments concerned, which
is hoped will shortly be signed. The International Offi
of Public Health in Paris—the technical body charg
with the revision of the Sanitary Conventions—being th
in enemy territory, U.N.R.R.A. was entrusted with t
work of revision, and early in 1944 its expert Commissi
on Quarantine, under the chairmanship of Dr. P. G. Sto
of the Ministry of Health, completed the work in a remar
ably short time. The drafts of the revised Conventio
were approved in principle by the Council of U.N.R.R.
at its second session in Montreal in September, 1944, a
were referred to the standing technical Committee
Health for final revision. Meanwhile Paris has be
liberated, and negotiations to safeguard the position
the Paris office and to ensure its collaboration wi
U.N.R.R.A. were successfully undertaken. Both t
English and the French texts of the revised Conventio
are equally authentic.

U.N.R.R.A., as a temporary measure until a full int
national sanitary conference can be called, will adminis
the new Conventions and receive and transmit intelligen
about epidemics. Such information will not, as hither
be confined to occurrences of the five "Convention" di
eases—plague, cholera, yellow fever, typhus, and sma
pox—but signatories are now under an obligation to not
U.N.R.R.A. immediately of the presence and course
any epidemic disease which may constitute a menace
other countries by its potential spread across frontie
Signatory Governments also undertake to pass on as reg
larly as possible statistics of all notifiable diseases occ
ring in their countries; U.N.R.R.A. will in turn distrib
its information to the Governments concerned. In ad
tion the Conventions make a new departure in that
U.N.R.R.A. is entrusted the delimitation of zones in whi
yellow fever is endemic, and the setting up of appro
standards of vaccine against yellow fever. Action h
already been taken in these matters by the Quaranti
Commission of U.N.R.R.A. The Conventions al
recommend the adoption by Governments of model int
national forms of certificates of immunization agai
various diseases.

The next session of the General Medical Council w
open on Tuesday, Feb. 27, at 10 a.m., when the Preside
Sir Herbert Lightfoot Eason, will take the chair.

---

ELIMINATION OF CROSS-INFECTION
AN EXPERIMENT

BY

H. P. PICKERILL, C.B.E., M.D., M.S., F.R.A.C.S.
Consulting Plastic Surgeon, Wellington Hospital, N.Z.

AND

CECILY M. PICKERILL, M.B., Ch.B.
Acting Plastic Surgeon, Wellington Hospital, N.Z.

The treatment of illness in hospital rather than in the home as many advantages. It also has one serious drawback. This the risk—sometimes slight, but in some classes of patient genuine and ever-present—of acquiring a fresh infection. To uppose that the great reforms of the latter part of the nineteenth century did away with this risk or even reduced it o minor proportions is a grave mistake. . . . The danger is reatest among children." (Leading article, *B.M.J.*, 1944, **1,** 97.) "We must ask ourselves whether, even if we had the most perfect hospitals and nursing, we would wish to keep hese infants for many weeks undergoing treatment, and hether that is economically and socially a sound procedure." Dr. Donald Paterson, *Proc. roy. Soc. Med.*, 1941, **35,** 49.)

All those whose work lies among infants and children in hospitals indeed realize to the full the truth of these statements, and the kind of surgical cases with which we personally have o deal are peculiarly liable to cross-infection in hospital wards. Many years ago we realized the truth of this in respect of left-palate cases, in which the upper raw nasal surface is just trap for all types of infectious organisms floating about hospital ward, and from which cross-infection, dehiscence, and sloughs are apt to ensue. Similar cases are hypospadias, angiomata, and syndactylism; for we are firm believers in arly operation in all of these—for the reasons that in infancy he patient is fully controllable by the mother, one has a comparatively passive subject to work upon, and the child grows up without any knowledge of deformity or disfigurement (a very important psychological point). All congenital eformities tend to get worse rather than better with age, and left until later childhood the mother has lost control and here are only fear and non-cooperation on the part of the atient—factors which make plastic surgery infinitely difficult.

We determined long ago to undertake no such cases in hospital ards. For many years all such infants have been nursed y their mothers either in their own homes or elsewhere. This of itself eliminated a very large amount of cross-infection—possibly 75%—but it was not entirely satisfactory. Conditions n some of the homes were far from desirable, and occasionally ome other member of the family would come home with bad cold, resulting eventually in an infection of the baby. he parents of these babies were for some inscrutable reason nearly always impecunious, with all the resulting restrictions of facilities for nursing; they rarely had telephones, and a ngle room in a nursing home was quite out of the picture. et these babies were worth making into useful members of ociety. We had had very many encouraging results—and also some reverses—for once a palate, for instance, has failed, he child is often doomed to take a very back seat in life, o matter how well developed he may be mentally or physically. We seemed to have reached an impasse. We felt that there as no reason why any cleft-palate, hare-lip, or hypospadias operation for infants should ever fail, provided that the right onditions could be obtained for their treatment. What we elt was necessary was some place where mothers could stay ith their babies in peace, cleanliness, and happiness, and with easonable facilities for treatment, and where extraneous ources of cross-infection could be rigidly controlled. We sought in vain for any support for such a scheme from private, fficial, and philanthropic sources. Then, on the advent of ocial security hospital benefits in New Zealand, we thought we saw our way to do what we wanted to do for these babies. But we did not want a hospital staffed in the usual way; we equired, and insisted, that each mother must nurse her own aby with as little extraneous interference as possible. But would the Government make benefits available to these mothers? After full investigation they did; and on behalf of the mothers and babies we wish to express our thanks to the New Zealand Health Department for their wise and valuable assistance.

The Scheme in Operation

Being assured that the greater part at least of the expenses of maintenance would be found, we obtained a suburban house with a reasonable-sized garden, and proceeded to convert it into something like what we considered was necessary to fill the bill. We now have accommodation for 12 mothers and babies. Each mother with her baby has a room to herself; some of the rooms are quite small, but all conform to the Health Department's requirements. Each has a large window facing the sun, and is daintily furnished—not at all like a hospital ward. We invite the mothers to come and nurse their babies just as if they were at home. No charge is made for maintenance, and only very occasionally are parents themselves able to pay any fees at all for treatment (some hospital boards pay very modified fees). A large workshop in the garden was converted into an isolation ward, but we have had to use it only once as such—for a mild case of chicken-pox, which did not spread. We have also built a small but very efficient theatre block in the garden. We are therefore fairly self-contained. The scheme has been in operation for three years, so that we can with fairness now perhaps estimate its value. The clinic has been full nearly the whole time; and so far there has not been a single case of cross-infection, local or general, not a single slough, not a single case of dehiscence. The worst that has happened has been the loss of a suture, and that only rarely, and no sign of what Sir W. de Courcy Wheeler called that other "bugbear of cleft-palate surgery—hyperpyrexia." There has been no failure with any cleft-palate or hypospadias case, nor loss of graft for angiomata or syndactyly. Post-operative antiseptics or sprays (beyond a little weak argyrol in the nose occasionally) are not used at all, so absence of infection cannot be due to their use. We do not claim to have reached perfection, for we are always endeavouring to better our methods and technique, but it is fairly certain that if 12 beds in a children's ward had been occupied with similar cases for three years, a considerable proportion would have been badly infected, either locally or generally, and therefore have been more or less failures. We believe that in some hospitals the infection rate is very high, though figures are difficult to obtain, and there was early last year much correspondence in the *Journal* about hospitals being dangerous places for infants. We therefore think that our experiment has justified itself, and we can claim to have so far eliminated the danger of hospital cross-infection in this class of case.

Other points to be noted as contributing to such results are:

1. All dressings are done in the theatre, under "theatre conditions."
2. Each baby is seen practically every day.
3. No mother or baby is permitted to come if either has a cold, and visitors are not encouraged.
4. Very great attention is paid to the feeding of the babies and to their weights. A strict rule is, "No gain in weight, no operation."
5. Mothers are encouraged to take their babies out in "prams" and to nurse them out of doors in the sunshine between operations.
6. Mothers must be kept happy. A disgruntled mother means a miserable and discontented baby, for whom any plastic operation would probably fail. This is possibly the hardest job of all, for one such mother may upset all the others. If she cannot be cured quickly (in two or three days at the most) we send her home; she comes back in a quite different frame of mind. Mostly, however, mothers are very glad of the rest and change and freedom from household cares, and co-operate splendidly in the work.

Comment

Prof. Grey Turner has recently stated (*Journal*, 1944, **2,** 92) that in Newcastle-upon-Tyne he also used to treat as outpatients many acute surgical conditions in infants as well as hernias and cleft palates—that is to say, he relied on the nursing of the mothers. He further states: "I believe that in most cases these little ones have a better chance if dealt with in this way, for they go back to an environment to which they are accustomed, and . . . receive the undivided attention of persons with whom they are thoroughly familiar." We think, though, that our plan of keeping mother and child together under as near ideal conditions as possible is an improvement—a step forward that is reflected in our greatly improved results during the past three years. An infant's environment is, and should be, its mother. We are using sedative drugs less and less, and often none at all. A baby is expected to be back on spoon feeding within eight hours of any operation.

The rationale of the whole scheme is based on the fact that a baby is born with a certain degree of passive immunity to its mother's organisms, and that it acquires further immunity in the next few months; and we endeavour to expose it to no other organisms whatever.

Since writing the foregoing account the Minister of Health has announced that in future his Department will defray the cost of treatment and maintenance of mothers and babies in our clinic.

A FACULTY OF OPHTHALMOLOGISTS

The following statement outlining a plan for the formation of a Faculty of Ophthalmologists has been received from the Council of British Ophthalmologists, whose honorary secretary is Mr. Frank W. Law, F.R.C.S.

There is obvious need for an authoritative and representative body to guide ophthalmologists through the intricate and important problems which are to be settled in the near future, to represent their interests to the State, and to co-ordinate their efforts, so that in the coming reorientation of the medical service of the country the greatest good accrues to the people, while at the same time the interests of the profession are preserved. It is generally accepted that, although circumstances may necessitate that changes be gradual, fundamental principles are now being evolved which will profoundly affect the medical profession and the community at large. So far as the ophthalmic services are concerned, the alternative to having policies imposed by others is to establish an authoritative body which will be able to initiate and criticize policy so that the interests both of the profession and of the community may be furthered.

The need for a body of this sort became apparent towards the end of the last war, and on the initiative of certain leading ophthalmic surgeons a general meeting of British ophthalmologists was held on May 2, 1918, at which it was decided to establish a Council of British Ophthalmologists, consisting of the Presidents and Past Presidents of the Ophthalmological Society of the United Kingdom and the Section of Ophthalmology of the Royal Society of Medicine, together with nine members elected annually, four each by the Councils of these bodies and one by the Council of the Oxford Congress. Later the Master and the Past Masters of the Oxford Congress were added as permanent members and the number of elected members was increased.

The functions of the Council, as stated in its rules, were "To take cognizance of, and to act in, all matters of ophthalmic interest arising in connexion with national industries and public services, and to initiate or to advise concerning movements which have for their object the welfare of the eyesight of the community." The Council of British Ophthalmologists has done much valuable work in many different fields—political, educational, and scientific; but recently it has been felt that this Council would have more weight and authority if it were more directly representative of the whole body of ophthalmologists in the country.

Some of the immediate problems which require examination and early solution are of great moment. The White Paper outlining the Government's proposal for a National Health Service deals vaguely with an ophthalmic service, although it is clear that it is the Government's intention to establish such a service. It will be the first task of the Faculty to examine the many questions arising in this connexion, and its aim, in collaboration with the appropriate Ministries and other bodies concerned, to play an important part in determining the form which this service will take. This raises questions not only of conditions of service but of the relation of the ophthalmic practitioner to the dispensing and sight-testing opticians, the methods of spectacle supply, the establishment and control of clinics, ar so on, all of which are of far-reaching importance. Moreov the institution of a National Service will raise the issue of t personnel who are to be considered as ophthalmologists, a the regionalization of hospital services will require adequa planning.

In addition to these medico-political matters it is evide that the questions of education and research, clinic and hospi policy, industrial problems, and a host of others are to assur importance in the immediate future. It is advisable that t whole body of ophthalmologists should play a part in the ins tution of such policies as they affect their specialty and be possession of a mechanism to influence their developme Organizations apart from ophthalmologists are taking an inter in such questions. It would seem of importance that the should be some body more representative than the Council British Ophthalmologists, as at present constituted, to gui the profession and advise the State. The Council of Briti Ophthalmologists has therefore decided to promote the form tion of a Faculty of Ophthalmologists.

Functions of the Faculty

The functions of the Faculty will be:

1. To take cognizance of, and to act in, any matters of ophthalm interest.
2. To encourage suitable standards of education in ophthalmolo for undergraduate and postgraduate students.
3. To encourage research in ophthalmology and cognate subjec
4. To secure such conditions in ophthalmic practice as will attra persons of high professional attainments and afford ample scope the exercise of their abilities.
5. To maintain a high ethical standard in ophthalmic practice.
6. To act as an authoritative body for the purpose of consultati in matters of public and professional ophthalmic interest.

Details of Constitution

The Faculty shall consist of Members and Associates w must be registered medical practitioners and have the followi qualifications:

Members.—Only ophthalmologists of full consultant status sh be eligible for membership. They shall be: (1) Ophthalmic surge to hospitals recognized as schools of ophthalmology by universit or other medical examining bodies. (2) Ophthalmic surgeons ot than the above who have been engaged for at least five years full-time practice as specialists and have charge of beds in volunta hospitals approved by the Council (at the initiation of the schen approved by the C.B.O.). Provisionally, these shall be gene hospitals of more than 200 beds and special ophthalmic hospit of more than 20 beds. (3) Persons no longer on the active staffs hospitals who have held appointments specified in Classes (1) and ((4) Other ophthalmic surgeons of consultant rank approved by t Council, including those in the Services or holding Governme appointments.

Associates.—Any ophthalmologist who has been for at least t years in full-time practice as a specialist (civilian or Service) sh be eligible for election as an Associate, on application in prescrib form and approval by the Council.

The above qualifications for Members and Associates are possi temporary standards which may require revision in case of t establishment of a national grading of consultants and specialists.

Executive Organization.—Executive powers shall be vested in council which, for the sake of continuity, shall be known as t Council of British Ophthalmologists. This Council shall consist 21 members, of whom 15 shall be elected by Members and 6 Associates of the Faculty.

Officers.—The officers of the Faculty shall be the President, Vi President, Hon. Secretary, and Hon. Treasurer, who shall be ele annually by the Council from among its members. Election to t Council shall be by postal ballot on a national basis, but with p vision as follows for regional representation. The electorate will divided into five regions. In the case of Members, the candid in each region who receives the highest number of votes in t national ballot shall be deemed elected as the representative of particular region. Thereafter the remaining seats on the Coun shall be filled by those other candidates receiving the highest nu bers of votes in the national ballot. In the case of Associates, candidate in each region receiving the largest number of votes the national ballot will be deemed elected, except in the Lond region, where the two candidates receiving the highest number votes will be deemed elected. As there will be five regions all six seats open to Associate candidates will thus be filled. One-th of the members of the Council shall retire each year. The memb of the Council to retire in every year shall be those who have be longest in office, but as between persons who became members of the Council on the same day, those to retire shall be determined by the Council by such method as it shall think fit. Members of the Council shall be eligible for re-election for a further period of three years, but after the second period of three years shall be eligible only after a lapse of one year.

The Council shall call an annual general meeting of the Faculty to receive and discuss its report. Any Member or Associate of the Faculty shall have the right to bring up for discussion at the annual meeting, after giving due notice to the Secretary, any subject within the province of the Faculty. The Council shall have the power to call a special general meeting of the Faculty at any time in case of need.

Standing Committees.—The Council shall appoint standing committees to deal with certain branches of its work. These committees shall have no independent executive power. Their function shall be to advise the Council on the subjects with which they deal. Any Member or Associate of the Faculty may be appointed to serve on them, but the chairman of every standing committee shall be a member of the Council. Persons not Members or Associates may be co-opted for temporary service on standing committees when required. The same rules shall apply with regard to period of service on a standing committee as in the case of the Council.

Special Committees.—The Council shall have power to appoint special committees to deal with special subjects and report thereon to the Council. Persons who are not Members or Associates of the Faculty may be invited to serve on special committees, and these committees may be given power to co-opt such persons.

Subscriptions.—Members of the Faculty shall pay an initial subscription of three guineas and Associates one of one guinea. The subsequent subscription shall be determined by the Council.

Co-operation and Organization

It is anticipated that the new Faculty will work in co-operation with the Universities, Royal Colleges, and Corporations of Great Britain and Northern Ireland, and maintain a close liaison with the Ophthalmic Group Committee of the British Medical Association.

The Council of British Ophthalmologists has appointed a special committee to organize the Faculty, to enrol Members and Associates, and to make the necessary arrangements as soon as possible for the election of the Council. When the new Council has been established it will assume all the functions of the present Council of British Ophthalmologists, which will hand over all its records and any other property in its possession.

Forms of application for enrolment as Members or Associates may be obtained from the Hon. Secretary of the organizing committee, Mr. Frank W. Law, 45, Lincoln's Inn Fields, London, W.C.2.

ORDER OF ST. JOHN

The following medical promotions in and appointments to the Venerable Order of the Hospital of St. John of Jerusalem have been announced:

As Knights, Major A. T. Smith, O.B.E., and Capt. R. Williams. *As Commander (Brother)*, J. P. Mitchell, O.B.E. *As Officers (Brothers)*, Drs. W. D. Jenkins and T. B. Sellors and Mr. W. F. J. Whitley. *As Serving Brothers*, Lieut. (local Major) J. C. B. Whycherley, R.A M C., Majors J. P. Quinn, *M.C.*, and J. Misquitta, Capt. G. R. H. Wrangham, Drs. R. G. Fear, L. A. Daly, T. S. Cochrane, C. Homi, J. Grant, I. M. Hughes, T. S. Taylor, H. L. Groom, R. Sells, W. D. Mitton, J. Prentice, W. O. Pitt, E. J. Blackaby, H. D. McCall, A. Madwar, M. C. Cooper, *M.C.*, H. R. Wynne, R. C. Allen, J. Pearce, R. R. M. Porter, *M.C.*, A. J. Struthers, H. M. Golding, D.F.C., and E. Schwartze. *As Associate Serving Brothers*, Drs. M. B. Jay, J. M. Raphael, B. L. Chopra, B. B. Sharma, and T. C. B. Chowdhary. *As Serving Sisters*, Drs. Doris Johns, Christina R. Laing, Mary A. C. Ainscow, Hilda Burnett, Catherine J. van Dyk, Jean S. Henderson.

The Welfare Equipment Development Association is the name given to an association of makers and distributors of welfare equipment which was set up at a meeting in London on Dec. 6. The meeting was the outcome of a report by interested manufacturers that there was ample scope for such a body, and it was suggested that among firms to be invited should be those interested in the manufacture of first-aid and medical equipment, sanitary equipment, and safety devices. Dr. R. A. Galway, who was among the speakers on Dec. 6, suggested many ways in which the association could harmonize the efforts of manufacturers and the requirements of welfare officers to give maximum benefit to workers. The offices are at 61, St. Paul's Churchyard, London, E.C.4, and the acting honorary secretary is Mr. A. D. Hinds.

Correspondence

A Common College Site and an Academy of Medicine

SIR,—The discussions taking place in the *Times* and elsewhere for the establishment of an Academy of Medicine and the bringing together of the three Royal Colleges on a common site, referred to in the *Journal* of Jan. 20 (p. 92), show that both proposals have influential support. The convenience and economy of a common site are so obvious that there is really no difference of opinion as to its desirability, but only as to its practicability from financial and other points of view. But the mere propinquity of the three Royal Colleges has little to do with and could have little influence on the establishment of an Academy of Medicine.

When the chief medical societies were amalgamated to form the Royal Society of Medicine the project was regarded by its founders as a step towards an Academy of Medicine. That this object has not been attained is due to many causes, one of which is the overwhelming prestige of the Royal Colleges of Physicians and of Surgeons and the lack of any enthusiastic official support from them. As Sir Stewart Duke-Elder has pointed out, some of the chief functions of an Academy of Medicine are "to uphold and foster the scientific progress of medicine, maintain professional standards . . . and stimulate the spirit of research." Sir Ernest Rock Carling has added another—to co-ordinate the various branches of medicine. While the Colleges of Physicians and Surgeons have for centuries opposed specialism, they themselves are the oldest examples of it. Now that specialism has inevitably become universal in all the sciences the active fostering of co-ordination has become at least as important as that of the specialties themselves—which indeed can quite well look after themselves. The Royal Society of Medicine has done more than any other body to co-ordinate the branches of medicine. It is therefore somewhat disheartening to a past-president to find that the part which the R.S.M. has already played and the far greater part which it might yet play in the formation of an Academy of Medicine have received no recognition in the discussions.

The fundamental and all-important functions of an Academy of Medicine are, however, *identical* with those of the Royal Society with regard to the physical and general biological sciences. Just as the active and energetic co-operation of scientists and their societies is indispensable to the success of the Royal Society, so is the co-operation not only of the Colleges and the Society of Medicine but also of many other scientific bodies for an Academy of Medicine. It is true that several scientific societies are neighbours of the Royal Society at Burlington House, but though this may be occasionally a convenience it is otherwise an almost negligible advantage. The common College site and the Academy of Medicine are both eminently desirable and deserve energetic support, but it will be a disservice to the latter to *exaggerate* the advantage to be derived from the former.—I am, etc.,

Far Headingley, Leeds. J. HERBERT PARSONS.

An Academy of Medicine

SIR,—The term "an academy of medicine" has a pleasing quality, although its modern advocates are hardly precise in the definitions they attach to it. On the other hand, it may surely be submitted that there already exists an organization which may claim in medicine an academic status—namely, the Royal Society of Medicine. An open platform, a democratic administration, freedom of debate with recorded and circulated records—what more can be desired?

In any event the last thing to be welcomed in the field of medical opinion would be a regime of authority.—I am, etc.,

Hove. C. O. HAWTHORNE.

The Oldest Medical College

SIR,—In the article "A Common College Site in London" in your issue of Jan. 20 you refer to the Royal College of Physicians of London as being "by far the oldest medical college in this country, for it was founded by Henry VIII in 1518." It must have escaped your memory that the Royal College of Surgeons of Edinburgh was founded in 1505, and is therefore thirteen years senior to the Royal College of Physicians of London. I draw your attention to the point in the interests of historical accuracy, and I shall be glad if you will accept a copy of the late Mr. Creswell's *Royal College of Surgeons, Edinburgh, 1505–1905*, which contains the relevant historical notes.—I am, etc.,

Edinburgh.
R. W. JOHNSTONE,
President, R.C.S.Ed.

Anaesthesia in Shock

SIR,—I am appalled at the complacency of Messrs. A. C. Crooke, C. J. O. R. Morris, and R. G. Bowler in their article of Nov. 25 (p. 863). Apparently they are so engrossed in their "scientific" investigations that they cannot see the wood for the trees. Their results and conclusions may or may not be of value to the profession, but there seems to be no excuse for allowing patients to die from lack of common sense and elementary clinical knowledge. Of the 5 illustrative cases, 3 died and 2 recovered. Clinical descriptions are apt to be misleading, but the following observations seem to be fair comment.

Case 1.—This patient was admitted at 10.15 a.m., "probably not severely shocked, because the surgeon left him." But he had a double compound fracture and a severe flesh wound, and at 4.15 p.m. (6 hours after admission) he was ashen grey and cold and his blood pressure was 50/45 mm. Hg. Three-quarters of an hour later somebody with a tiny spark of clinical acumen "made an attempt to start a transfusion," but after 2 hours the patient had received only 924 c.cm. of fluid, of which 686 c.cm. was plasma and the rest blood. At this time the blood pressure was still only 60/40 mm. Hg, but the patient was "even smiling at the doctors," so they stopped his life-saving transfusion and operated on him and he died on the table. His minor wounds were "cleaned and sutured," but the major "compound fracture with much laceration of tissue" was not touched.

Surely it is common knowledge in the profession that a patient with a compound fracture and a severe flesh wound who is ashen grey and cold and has a blood pressure of 50/45 mm. Hg requires early and rapid transfusion of blood, and operation as soon as the blood pressure reaches the 100 mark: Also the transfusion should be continued *during* the operation and for a short time afterwards.

Case 2.—This patient was admitted at 1.45 a.m. He was drowsy and ashen-coloured and his blood pressure was 60 mm. Hg, but as there was "no obvious haemorrhage" he was left until 6 a.m. before transfusion was started. But he had a compound fracture of the right forearm with a severe injury of the right hand. There were also multiple wounds of the right leg of such severity that the vitality of the leg was abolished. He must have lost a lot of blood before admission. At 8 a.m.—i.e., over 6 hours after admission—he had received only 2 pints of blood, but the transfusion was stopped. Three hours later a plasma transfusion was started, and during the next 10½ hours, while "investigations" were being carried out, 3 pints of plasma were given slowly. Eventually, 20¼ hours after admission, he was operated on with a blood pressure of 100/55 mm. Hg. But between 6 a.m. and 9.30 p.m. (time of operation) his blood pressure had fluctuated between 105 mm. Hg and 130 mm. Hg. The day after operation "he was too ill to have his gangrenous leg amputated."

What a sorry story of fiddling while Rome burns! Again, the severity of the injuries demanded early transfusion and operation, and the essential part of the latter was the removal of the gangrenous leg as quickly as possible. To wait 20 hours and then to omit the essential part of the operation is just incomprehensible.

Case 5.—Intravenous pentothal is not the best anaesthetic for an old man of 67 who has a fractured femur. To repeat the dose 4 days later in order to correct a malposition which could well have waited 10 days was to court disaster.

Cases 3 and 4 were admitted with a blood pressure of over 100, and seem to have been suffering from so little clinical evidence of shock that they were able to withstand investigation of their non-existing shock.

Finally, in their conclusive recommendation of cyclopropane and oxygen as the best anaesthetic for the severely shocked patient, Messrs. Crooke, Morris, and Bowler make the astonishing remark (astonishing after 5 years of war) that "in modern war it is possible for the great majority of patients to be brought back for operations to base hospitals." Do these gentlemen not yet realize that compound fractures, severe flesh wounds, and amputations are operated upon in the forward areas, where the anaesthetist has neither cyclopropane nor nitrous oxide at his disposal? Yet the mortality rate in such cases is less than 1%.—I am, etc.,

B.L.A.
R. STRANG,
Major, R.A.M.C.

SIR,—Dr. D. C. Devitt asserts (*Journal*, Dec. 16, p. 798) that the conclusions reached in our article on general anaesthesia in shock are based on only 26 cases. These cases, on which he bases his criticisms, formed a control group which were not shocked and had normal plasma volumes. For reasons of space we reported fully only 5 cases of shock from a wide experience. These cases were chosen to demonstrate the greater tendency of anaesthetics to lower blood pressure when the plasma volume was reduced. The only "far-reaching conclusion" to which we have come is that anaesthetics affect the blood pressure mainly through the vasomotor system, and we consider that the evidence which we have presented is adequate.

In reply to Major Strang's letter, I should like to state that we are in agreement with a number of his criticisms, but would point out that they should be directed to the clinicians in charge of the cases. We went as independent observers and had no control over the management of any of the three cases in question, which were all seen in outlying hospitals. I would urge Major Strang, however, to be more careful of his facts; thus, in Case 1 he states that "after 2 hours the patient had received only 924 c.cm. of fluid, of which 686 c.cm. was plasma and the rest blood." This is very different from the statement made in our paper. The patient actually received sufficient fluid by transfusion to restore the plasma volume to normal. We selected this case as an example of mismanagement in another way—namely, the choice of anaesthetic.—I am, etc.,

London Hospital, E.1.
A. C. CROOKE.

War Malaria

SIR,—Sir Philip Manson-Bahr's contribution to war malaria (Sept. 9, 1944, p. 350) is indeed welcome, as it expresses the common sense of the position. In Egypt it was not my business to treat malaria cases, but it was my business to advise the D.M.S. what was to be done with them. I soon found (what Sir Philip Manson-Bahr now states) that benign tertian malaria is more of a nuisance than a serious disease, except in the uncommon cases where there is some complication.

The matter came under my notice when travelling in Egypt, when the medical officers in the hospital trains, who were well informed, asked me to deal with the men they called the "round trippers." What actually happened was that some with benign tertian malaria were sent to Egypt and taken into hospital. They were carefully examined—I think in some instances by men who had never seen malaria cases. As they could find nothing the matter with the men they sent them back again. They got as far as the Canal, where a glass of water, etc., brought on another attack. They were sent back to a hospital in Egypt, usually not the hospital which discharged them. The result was that the hospital trains were littered up with these cases. I had a discussion with the chief, and the following procedure was arranged.

They were all put into garrison battalions and set to work. A small detention hospital was provided, and whenever they got an attack they were put into hospital. As soon as they were right they were put to work. The effect was twofold: it helped to eliminate malaria and prevented men from thinking they had a serious disease, and the "round trippers" were eliminated.

As Sir Philip Manson-Bahr says, malignant malaria is a different disease. It is protean and it can be very deadly. It may have been on his advice—that I cannot say—but the instructions were that if a soldier was sent to a forward station and had a rise of temperature he was immediately given quinine. If you waited until you found out whether he had malaria and what type of malaria it was, it was sometimes too late. The benign tertian cases which returned to Australia from that campaign have gradually disappeared, but I can only say that malignant malaria engenders profound respect in anyone who has to deal with it.

The extent of malaria can be gathered from the fact that the day after Armistice, when we left Egypt, there were 54,000 men in bed, mostly malaria cases, and that the Medical Research Council of Great Britain informed me that there were 650,000,000 cases on the globe and 4,000,000 deaths annually. But it is obvious that in such places as India and Malaya it is difficult to see which type you are dealing with. I believe in the epidemic in Ceylon 2,000,000 of the 5,000,000 people suffered from malaria, and 100,000 died. The details are not known to me.

Sir Philip Manson-Bahr rendered a great service in clearing up the problem, which for a time was a source of worry to the Army in Egypt.—I am, etc.,

Melbourne. JAMES W. BARRETT.

Terminology in Malaria

SIR,—In your annotation on terminology in malaria (Jan. 20, p. 88) you refer with approval to more precise descriptions of the various forms of malaria as *vivax* malaria, *falciparum* malaria, etc., "in place of such clumsy and archaic names as 'simple tertian,' 'benign tertian,' and the like." A recent attempt I made to employ this more precise nomenclature in the commentary for a medical film had to be abandoned because in the case of quartan malaria the phrase *malariae* malaria proved to be a cause of confusion, and well-nigh impossible to enunciate clearly. This difficulty might be avoided by referring to the four common forms of malaria as *vivax*-tertian, *falciparum*-tertian, *ovale*-tertian, and *malariae*-quartan—terms certainly less archaic but scarcely less clumsy than the old familiar names "benign tertian," "malignant tertian," "ovale tertian," and "quartan."—I am, etc.,

School of Tropical Medicine, Liverpool. J. W. S. MACFIE.

Prisoner-of-War Mentality

SIR,—I have read Major D. L. Charters's letter (Jan. 6, p. 24) with great interest. Briefly speaking, it is an objection raised to a statement made by Dr. Harkness in a letter last April. The statement he quotes is as follows: "The very large majority of our returned prisoners of war will be problems for their lifetime."

I agree with Major Charters that such a statement is pessimistic and probably far from the truth. I do not believe that a large majority or even a majority, but a very definite minority, remain problems for their lifetime. There can be no accurate statistics to prove such a statement either way; but I would be quite prepared to believe the figure well under 10%. An article appeared in the *Journal* of Jan. 1, 1944 (p. 8), and was written some six months after I had returned from a prison camp. In that article emphasis was laid on the problems of the period following repatriation. The repatriates' reactions were called "release phenomena." The period was likened to that time when a man is released from a caisson and shows symptoms of caisson disease. It was stressed that this was not really a disease but normal phenomena shown by a normal body as a result of release from an abnormal external environment. I hope I shall in no way offend or hurt Major Charters and his companions who join him in giving evidence against Dr. Harkness's statement if I point out that they are still within the caisson and are unable to judge accurately what are to be their reactions after release.

At the time that article was written I was myself passing through the period of reaction. Since then I have taken much interest in this subject and have met many returned prisoners of war, and can perhaps now convey an impression somewhat nearer the truth. Prisoner-of-war life probably exaggerates neurotic and psychopathic tendencies. It is the small minority with these latent weaknesses who may show symptoms of such for the rest of their lives. It is for these cases that I thought fit to suggest that there should be set up after the war a special rehabilitation centre with a psychological staff in attendance. The average man, who is in the large majority, on repatriation shows release phenomena. It should be stressed once more that these are not neurotic or psychopathic phenomena, but a normal response of a normal man to release from an abnormal external environment. It might even be termed an over-swing due to the inertia of failing to adapt immediately to a different environment. These symptoms are not those of mental abnormality and do not need specialist treatment. There may in some cases, however, as described previously, be some need of a "long-distance guidance." These symptoms will pass away and leave no trace. It seems evident that a tendency to show these phenomena is present in everyone, and that many do show them to a degree sufficient to be remarked upon.

These symptoms are the result of many factors, among which are: (1) An abnormally high morale due to sudden cessation of a hard life. This, keyed up by an idealistic image of their home country, gives rise to an impatience at the slow rate of progress and lack of enthusiasm at home. (2) An impatience to catch up after so much wasted time resulting in a tendency to cut corners in the accepted style of normal business and social life. (3) Not merely a lack of respect for authority but an actively encouraged disrespect and spirit of sabotage against authority. Running parallel but in opposition to these positive entities is a negative spirit, one of lethargy and apathy, born of years of frustration. These positive reactionary symptoms may therefore be considered as normal to the repatriate during a certain period of time.

In the same article I stated that at this time a man needs sympathy. It was an ill-chosen word. The repatriate himself wants not sympathy but a square deal and a job to get on with. He does not want charitable sympathy but a sympathetic understanding, an acceptance and a recognition of his value. With this in mind, the community will gain the confidence of the returning prisoner of war and reap the benefit from his latent spirit of high morale. Without this understanding there is a risk that he will join the lines of the discontented and thereby become a problem for the rest of his life. The repatriate wishes to rejoin the queue where he left it years ago, not at the back.—I am, etc.,

P. H. NEWMAN,
Major, R.A.M.C.

Psychology's Opportunity

SIR,—Dr. A. C. Wilson's letter (Jan. 20, p. 96) is as timely as it is trenchant, for not only does he indicate the source of many of the ills of the present-day world but he also points the way whereby they may be extirpated. Psychologists have long recognized that basically war, with all its implications, results from causes due to social maladjustments of persons and peoples. Freud, Ernest Jones, Glover, and many others have clearly demonstrated this in their writings and pointed a moral, but unfortunately their warnings have not been heeded, for those very evils which promote racial aggression and subsequently war still flourish unchecked.

With the exception of Soviet Russia the countries of the Western Hemisphere continue to labour under the yoke of an archaic ecclesiastical rule, which for centuries has imposed its taboos, fetishes, and imperfections upon mankind. In no country was this domination more shamefully abused than in Russia prior to the Revolution, but there to-day the greatest social experiment of all time is being carried out with results apparent for all to witness. There the aggressive instincts of a race have been sublimated into constructive channels, and the health and happiness and general welfare of the populace immeasurably improved thereby. In modern Russia, as Dr. Wilson points out, the psychologist has been heeded, and advanced thinking rather than a blind devotion to outworn social, economic, and religious creeds has wrought changes which must become the model for the rest of the world.

What great prospects await us here, too, if progressively minded men are but chosen to guide! Their task will be a hard one, however, for not only will they need to be equipped with a deep psychological understanding of the problems of to-day but they will also require force and courage to break down the centuries-old barriers which obstruct their path. That the present guardians of the barriers have failed is all too apparent to those who survey the present misery of the world, and the tragedy of the situation is intensified by the knowledge that such horror might have been averted. Greed in any section of society inevitably engenders hate and fear in others, and from these unholy twins springs that form of undesirable aggression which leads to war.

These processes must be clearly understood if the world is to be freed from recurring tragedies such as that which engrosses civilization to-day, and modern thought should eventually prove capable of averting such disasters, but the old order must go and reason must prevail in its stead; with the growth of knowledge among the people as a whole the ultimate salvation of mankind will be achieved.

It is a significant fact that from the mass of literature written on this subject during the past decade only that which recognizes psychological concepts regarding the causes of war has proved accurate in its anticipations or genuinely constructive in its prophylactic suggestions. The soldiers, churchmen, politicians, and "big business" men have all failed because consciously or subconsciously they were activated by selfish motives; the psychologist has none of these, so why not follow Russia's example and give him his due place in the vast problems which will follow in the wake of peace?—I am, etc.,

A. TANDY CANNON.

*** Nevertheless we may well be thankful that the aggressive instinct of the Russian is so much in evidence on the Eastern front at the moment.—ED., *B.M.J.*

Relation of Neurology to Psychiatry

SIR,—In reply to Dr. F. A. Pickworth (Jan. 20, p. 95), whose views as to the frequency of incidence of organic lesions in the brains of mentally disordered persons seemingly differ from my own, I would suggest that much depends upon what one interprets as significant. This matter of interpretation is beset by many pitfalls and fallacies. Not least of these is the confused picture that results from lesions occasioned by the illness from which the patient died, as against those, if any, which truly appertain to the mental disorder as such. It is, of course, unusual for mental disorder *per se* to kill the patient save in certain well-recognized forms. Other fallacies relate to agonal and to post-mortem changes, also to changes occasioned by the process of fixation of tissues—to mention just a few to which the brain is specially vulnerable.

Even if all the lesions found could indubitably be regarded as related to the symptoms of disordered mind—and this indeed is a great supposition—the questions then arise, "In what temporal order did those lesions occur? Did the organic changes precede or follow the psychical? These questions are of the utmost importance as regards aetiology. It may be that the organic lesion is itself but the end-product of prolonged and repeated dysfunction, such as capillary spasm with ischaemia or arteriosclerosis following hyperpiesia, both of which may occur in states of emotional tension and lead either to actual degenerative lesions or to increased tissue susceptibility to other noxious agents. The application of dynamic conceptions to the field of organic pathological change has not nearly received sufficient attention.—I am, etc.,

Warlingham Park Hospital. WM. H. SHEPLEY.

Absence of Surgical Shock in Epileptics

SIR,—In view of the criticism by Mr. H. Haxton (Jan. 13, p. 61) of the inference I made (Dec. 30, p. 867) that absence of shock in my case of injury while in a major epileptic fit supported the theory of the nervous actuation of shock, may I amplify my reasons.

I did not mean to suggest, as Mr. Haxton implies, that the almost severed limb distal to the site of injury (which I described as cold and bloodless) could in any circumstances have come into the clinical picture. It was the extensive trauma to the muscles round the shoulder and to the joint itself, proximal to the point of severance, that I should have expected to produce severe shock, the absence of which I attributed to the epileptic state of the patient.

As a practising surgeon with a clinical rather than an experimental approach to the subject of shock, I should like to record my hesitation in accepting the "toxic" theory as the major cause of shock, based as it is upon animal experiments which seldom appear conclusive. For instance, the experiments quoted by Mr. Haxton in support of this theory, in which decerebrate animals suffer shock if the blood supply to an injured limb is maintained, are offset by others in which shock develops after release of a clamped artery supplying a traumatized limb, but is not increased when the vein too is released. May not the path of the centripetal shock-causing impulse travel by the sympathetic nerves accompanying the artery? This sympathetic route is favoured by: (1) the pain and mild shock sometimes caused by the clamping of an artery while operating under local anaesthesia, and (2) the severe shock often produced by traction on the upper abdominal mesentery during laparotomy.

As a clinician, I find it very hard to square with the "toxic" theory cases of shock approaching the fatal in degree which occur from time to time from purely psychological causes, and those in which the circulation, as in a volvulus of small gut, is automatically occluded. Again, the wide variation in the degree of shock produced by similar injuries in individuals of contrasting psychological make-up is much more suggestive of a nervous than a chemical onslaught.

While admitting, therefore, that the prolongation of shock may often depend on some toxic product, I prefer to consider that its first onset is more often actuated by some nerve impulse.—I am, etc.,

Beccles, Suffolk. C. GRANTHAM-HILL.

Supervision of Mental Defectives

SIR,—Dr. J. S. Cookson's article (Jan. 20, p. 90) deals so briefly with a subject with so many facets that it begs for amplification. His plea seems to be for the subsidization by the local authority of employment for mental defectives who at present readily find a full-time occupation owing to labour shortage, but who, when labour conditions return to normal, will be unable to compete for employment with those of adequate intelligence except in carefully selected individual jobs, which naturally will be few. Dr. Cookson quotes the view that institutional (colony) training tends to adapt the defective to the needs of the institution. His figures are for defectives (adults) ascertained in childhood who are not under certificate and who presumably have never received institutional care and training. Perhaps the following figures might supplement Dr. Cookson's, and show the picture of employment from a colony source within the same geographical area.

Out of 477 adult male defectives of all grades at present on the books of this colony 46 are on licence living with parents or employers where the nature of employment is that normally done by adults and is full time, 35 are at various agricultural workers' hostels, and 27 are going out from the colony to daily full-time work normally that of an adult, giving a proportion of 22% employability from "institutionalized" defectives to compare with Dr. Cookson's 48 out of 227, or 21%. Dr. Cookson's lowest mental level is 5 years, and one assumes that his 227 ascertained defectives under statutory supervision are not the grosser types who are for the most part in institutional care in any case.

As well as supplementing Dr. Cookson's figures I think this may be taken as refuting the belief that institutional employment leads only to "institutionalization."—I am, etc.,

J. JOHNSTON MASON,
Westbury-on-Trym, Bristol. Medical Superintendent, Brentry Colony.

Hypoproteinaemia in Severe Anaemia

SIR,—Dr. T. Davies's article (Jan. 13, p. 45) has stimulated me to record a similar case.

A woman aged 48 was admitted to hospital on Nov. 10, 1944, with a history of ten years' menorrhagia. She has been "anaemic" for years and used to "swell upwards" some days *after the periods stopped*—i.e., while protein was taken up in the formation of haemoglobin. On examination her conjunctivae were pale, so were the nail beds and palms; koilonychia was present; superficial glossitis was evident. Generalized oedema stopped at the level of the 4th intercostal space. Her thigh measured 36½ in. and the abdomen was 46 in. in girth. There was cervical congestion of 4 in. above the manubrium and some cardiac enlargement. A haemic systolic murmur was heard at the apex. B.P. 130/70. No hydrothorax or ascites, the abdominal girth being due to oedema of the wall. The blood picture was Hb 31%; R.B.C. 3,150,000; C.I. 0.5; icterus index 15 U.; Wintrobe vol. index 0.8; plasma proteins (copper sulphate method) 5.40; cholesterol 100 mg. per 100 c.cm.; van den Bergh positive indirect 5.6 units. The urine excretion was 30 oz.; no abnormal constituents. Jaundice became clinically obvious. The patient felt very poorly and she was grossly orthopnoeic. On Brig. Whitby's advice one pint of whole blood group O was given, followed by *double-strength* reconstituted plasma. A high protein diet was started and supplemented by ferrous sulphate, HCl, vitamin C, thyroid, and desiccated hog's stomach. On Nov. 23 Hb 55%; R.B.C. 4,500,000; plasma protein 5.8%; thigh girth 30 in., abdomen 41 in.; urine output 40 to 45 oz. daily.

It was noticed that oedema remained more pronounced on the left side, and it was suggested that a fibromyoma might be pressing on the left venous and lymphatic return and also accounting for menorrhagia with the whole sequence of events. This was subsequently confirmed when pelvic examination became possible. On Dec. 19 the patient was discharged with practically her normal measurements, "fitter than ever before," and with a healthy red colour in her cheeks.—I am, etc.,

Dorset County Hospital, Dorchester. D. CAPPON.

Artificial Insemination

SIR,—May I say how I, and I am sure many others, welcome the letter of Dr. Leonard G. Parsons (Jan. 20, p. 96) and the breath of wholesome common sense and moral indignation it brings to the discussion on artificial insemination that has been conducted in recent numbers of the *Journal*. It is difficult to argue with the advocates of this latest novelty in techniques offered to the community, for they seem to have no clear ethical principles and, we may be sure, will be disdainful of those that have. To invoke the Christian ethic, as Dr. Parsons has had the courage to do, will elicit nothing but jibes from them, and yet it must be invoked if medicine is not to become the servant of hedonism.

The legal sanction is the only one likely to appeal to the advocates of extramarital insemination; but even the law may alter, as we saw when the speculation that a pregnant girl, stated to have been raped, might develop a neurosis was equated with "danger to life," and the artificial termination of her pregnancy pronounced lawful.

The logical conclusion of this advocacy of artificial insemination is the human stud farm, with the making of a stud book, and the State registration of semen donors. We shall then have a new profession (or shall we call it a trade?) of donors, presumably a very select one, for those who do not blush to adopt it. A new medical specialty will follow (with a new-coined Greek or Latin name), asking for a special diploma from the relevant examining bodies, and, in due course, for its own special place in the medical curriculum. Thus "medicine" advances from triumph to triumph and retreats from decency after decency. —I am, etc.,

London, W.1. F. M. R. WALSHE.

SIR,—Mr. T. C. Clare (Jan. 13, p. 62) asks at what age a child, the result of A.I.D., should be told the circumstances of his or her birth. In my experience as certifying factory surgeon I found that most adopted children had not been told that they were illegitimate before they left school. If the parents follow the instructions of the A.I.D. surgeons to have the child registered in the husband's name, there will be no need to inform the child at any time. But is this instruction not an incitement to commit a felony?—I am, etc.,

Birmingham. ROBERT ANDERSON.

SIR,—Many aspects of artificial insemination have been discussed, but one aspect has been ignored until Mr. T. C. Clare called attention to it. The effect of this scientific experiment on its victim is surely of vital importance. It has been somewhat airily assumed that he would know nothing of it, but this is most unlikely. "Murder will out": he is obviously illegitimate, and this cannot be concealed without criminal liability involving both parent and doctor. For this reason alone I advise no medical man to have anything to do with it. What would be the reaction of a young man or girl to the knowledge that they were the offspring of a test-tube supplied by some unknown man, and what would they think of their mother? It is difficult to believe that any decent man would lend himself to this proceeding; even the tempting possibility of being the father of 400 children a week, so alluringly mentioned by one of your contributors, would not seduce him to join a stud farm. Surely, if a couple are prepared to accept the intervention of a third person it would be most natural to let this man operate in the natural way; morally I can see no difference.

One might make another point: suppose the woman was not satisfied with one child and wanted three or four—who is to limit her? And one may reasonably assume several donors; it would certainly be a very interesting family, but how would it work?—I am, etc.,

Brighton. J. A. ROOTH.

SIR,—I have read the correspondence about the above and the article in the *Journal* of Jan. 13 (p. 40). I find myself in complete agreement with the able letter of Dr. Leonard G. Parsons (Jan. 20, p. 96). In my opinion this procedure is illegal, immoral, and disgusting. I consider it is wrong to introduce into the human body living organisms except in the natural way. One of your correspondents compares this procedure with the crime of murder, and suggests extenuating circumstances; I cannot conceive any similar extenuating circumstances, but by this statement he certainly admits the illegality of the procedure.

The care of the health of the people is the doctor's job, not the production of artificial babies. The general suggestion seems to be that the profession should adopt their own moral code. I am afraid we are deteriorating rapidly.—I am, etc.,

York. F. J. WILFRID SASS.

SIR,—What a picture this subject conjures up! A man masturbating—as a "favour" or for a fee; the fertilization of another man's wife by his semen, artificially introduced by a doctor who is blind to the moral issues raised thereby; registration of the child in the name of the woman's husband, but not of the real father; and, finally, the life-long mental effect that must be produced in both the man and his wife from the knowledge that the child is not *their* child but the mediate adulterous offspring of a stranger! The most surprising thing is that there should be members of our profession who apparently are willing to lend themselves to such a form of procuration, and, over and above it all, are not ashamed to write to the medical press and boast of their share in such iniquity.—I am, etc.,

Brookwood, Surrey. H. M. STANLEY TURNER.

SIR,—I take the strongest exception to the pages of the *B.M.J.* being used to propound the pagan way of life. Your contributors on artificial insemination (donor) (Jan. 13, p. 40) have said nothing particularly original except perhaps to suggest that the marriage service in the Book of Common Prayer means just nothing to them. Personally I regard this article as the most diabolical thing I have ever read, and it must offend every member who even half-heartedly favours the Christian view of the family. The whole article reeks of vicious expediency, half-truth, and advocacy of plain lying—e.g., birth registration—a scheme of things which if tolerated would not enhance our reputations with the laity.—I am, etc.,

Stourbridge. C. F. KEANE.

Handbook on the Care of Laboratory Animals

SIR,—Last year we wrote to all holders of the Home Office licence asking them to send us information for use in the forthcoming handbook. Thanks to valuable help from workers in Britain and also in America, Russia, and elsewhere, it has been possible to deal with most if not all of the smaller laboratory animals; but we are anxious to get into touch with those who have been successful in maintaining healthy stocks of the larger species—cats, dogs, the smaller ungulates and primates. These species will not be dealt with in detail in the handbook, but we should like to include references to published accounts of methods of maintaining healthy and contented stocks and also to mention laboratories at which advice on the subject can be given at first hand. We should be most grateful if those who could help in either of these ways would get into touch with us as soon as possible.—We are, etc.,

C. W. HUME,
Hon. Secretary,
F. JEAN VINTER,
Secretary,
Universities Federation for Animal Welfare.

284, Regent's Park Road,
London, N.3.

Future of the G.P. Specialist

SIR,—Mr. J. K. B. Waddington's letter (Jan. 20, p. 97) ventilates a most important problem which does not appear to have received any consideration by the Government in the White Paper. There are several hundreds of experienced surgeons, physicians, and anaesthetists attached to hospitals performing splendid work while at the same time engaged in general practice. Their future appears to be nobody's concern. Recently a colleague engaged in general practice operated successfully on an eminent physician and an equally eminent ear, nose, and throat surgeon. Such skill must not be put aside because the possessor of it is also engaged in general practice.

I suggest that all such physicians, surgeons, and anaesthetists should join together to voice their views and state a case to the Government through the Negotiating Committee. I am prepared to organize a united effort to be presented to the British Medical Association if I receive support from members of hospital staffs.—I am, etc.,

New Place, Horsham, Sussex. GERALD DELACEY.

Death of Robert Burns

SIR,—In reply to Dr. Archibald Ogg's letter to the *Journal* of Jan. 13 (p. 62), may I suggest that the late much-respected Sir James Crichton-Browne viewed the matter of Burns's last illness as a somewhat prejudiced historian working with scant material rather than as a cold clinician doing the same, using other men's unsubstantiated facts?

The words "rheumatic endocarditis" indicate what is only symptomatic of an acute valvulitis in the one case, of cicatrized valves in the other, chronic, case; being simply a label, a part diagnosis recording an incident in the course of the illness and not the disease itself. A fact well known to practising medical men is this: that scarred heart-valve cusps occurring as a sequel to acute articular rheumatism (rheumatic fever) commonly dispose to and determine the site of a bacterial endocarditis many years after. However, we need not "split straws": clearly, Burns died of an actively infective disease of the whole heart, not from alcoholism, which itself could have neither provoked nor excited the disease. Thus far, I dare say, Dr. Ogg would agree with me; then we can forget it, and turn again to enjoy Burns's delightful poetry.

In reply to Dr. Letitia Fairfield's letter (Jan. 20, p. 98), may I point out that she, unreasonably as I think, places the blame for Burns's death on the doctors; meaning, I suppose, Dr. Maxwell, though he without doubt would advise to the best of his ability in conformity with the then medical teaching. Gentle and generous towards the sick poet as he was known to be, the doctor was much liked by Burns, who named his posthumous child after him—a deed which speaks for itself.

Perhaps the "tonic treatment" ordered—crude as it was to include sea-bathing, horseback exercise, iron water and port-wine together—might in some circles be fancied even to-day as being not unorthodox and likely to be helpful, though in Burns's case unsuited to his condition of health at the particular time when he was out of the doctor's sight, away from his professional supervision. Could the doctor be held blameworthy for this? I think not. Though unsuitable in relapse, the prescribed treatment was probably believed suited to his case before Burns left for the Solway. Dr. Fairfield's statement will call to the minds of medical men with long experience of practice instances where they have been wrongly held responsible for causing the patient's disease, let alone his death.—I am, etc.,

Bournemouth. S. WATSON SMITH.

The latest news bulletin concerning the Friends' Ambulance Unit (4, Gordon Square, London, W.C.1) gives a record of work by the oversea section, whose members now number more than 500. Throughout last year the main increases in oversea personnel were made in response to demands in the field of European relief. Among other items of information from various parts of the world is a first-hand account of conditions in Tengchung, a large city retaken by the Chinese on the Yunnan front, where the F.A.U. is initiating some measures of medical relief. The chairman has returned from a four-months tour of Mediterranean sections and Ethiopia. The annual report of the F.A.U. for 1944 was published on Jan. 23.

Medico-Legal

BUSINESS OR PROFESSION?

An optician practised in St. Helens. The income-tax authoritie said he was carrying on a business, and assessed him for exces profits tax. He appealed to the Inland Revenue Commissioners, an they held that he was carrying on a profession. The departmen took the case to the High Court, where Mr. Justice Macnaghten sai that, although the Commissioners had found as a fact that he wa carrying on a profession, the right view of the case was that h was conducting the business of selling spectacles. The learne judge's decision necessarily meant that there was no evidence o which the Commissioners could have found that the optician wa carrying on a profession, for if there had been any such evidenc his Lordship would not have been entitled to upset their finding The optician appealed to the Court of Appeal, who said that th Commissioners had evidence before them upon which they coul reach their conclusion, and its correctness was therefore not a matte of opinion. The Court accordingly held that the optician had bee practising a profession and therefore could not be assessed for exces profits tax.

As their Lordships went fairly fully into the distinction betwee a business and a profession, their decision has general importanc The essential notion of a business, within the meaning of the Financ (No. 2) Act, 1939, S. 12 (3), is that it is commercial in characte Lord Justice Scott said the section left in his mind a strong impres sion that the primary object of the excess profits tax was to dea with profits which were likely to be greatly augmented by the effec of war upon supply and demand without any relation to the effor of the owner of the business. That view, he thought, was con sistent with the characteristic of the tax that professions, whic essentially depended upon skilled but non-commercial individu initiative, should be exempt. Six considerations pointed to th optician's carrying on a profession. There was no advertising, eve outside the premises; he had the appropriate waiting-room and tw consulting-rooms; no prices were mentioned in connexion with th seven or eight types of frame exhibited in his little windows for th observation of patients. He carried out the functions of examinin and testing eyesight and prescribing the suitable glasses an assembling them in their frames—meaning, no doubt, for exampl that they were set in the frames at the appropriate angle, which c course was essential. His net earnings were very substantia particularly in relation to his expenditure on material—what woul be called the stock-in-trade of a business; and the proportion betwee those earnings and the item for stock-in-trade was far larger tha it would normally be in any trading business. The Court of Appe disagreed with the Solicitor-General, who argued for the Crow that the livelihood of a professional person was attributable to h intellectual qualifications. A professional man, they said, migl utilize aesthetic qualifications, and one who dealt with a subjec matter cognate to medicine might use many other qualification They therefore disagreed with the judge's finding that as a matt of law an optician is not carrying on a profession.

The Services

Temp. Surg. Lieut. M. J. Brosnan, R.N.V.R., has been appoint M.B.E. (Military Division) for great courage and devotion to du in organizing rescue parties and in first aid to the injured wh H.M.S. *Blackwood* was lost.

Temp. Surg. Lieut. R. C. P. Aldridge, R.N.V.R., has been me tioned in dispatches for good services during operations in Italy.

Col. (Acting) D. P. Levack, R.A.M.C., has been appointed C.B. (Military Division) in recognition of gallant and distinguished se vices in the field.

Major (Temp. Lieut.-Col.) J. A. Chapel, M.B.E., R.A.M.C., h been appointed O.B.E. (Military Division) in recognition of disti guished services.

The Efficiency Decoration of the Territorial Army has been co ferred upon the following: Lieut.-Col. E. Walsh; Majors (Tem Lieut.-Cols.) A. H. Charles, E. J. G. Glass, F. W. A. Warren, a J. F. Wilde, R.A.M.C.; Major H. P. Gabb, M.C.; and Capts. Jack and J. H. B. Livingston, T.A.R.O.

CASUALTIES IN THE MEDICAL SERVICES

Major BARNETT FREEDMAN, who died over-seas on Dec. 2, 194 aged 30, was, at the time of his death, Deputy Assistant Director Medical Services (Nutrition) at Headquarters, Allied Land Forc outh-East Asia Command. He studied medicine at the Middlesex ospital from 1934 until he qualified M.R.C.S., L.R.C.P. in 1939. fter working as R.M.O. at the Albert Dock Hospital during the eriod of intense air raids on the docks area, he joined the R.A.M.C. n Dec., 1940. In the Army he served first in Wales and then went broad in April, 1942. Arriving in India, he was posted to the orth-West Frontier and spent a year there. His special interest in nd knowledge of nutrition caused him to be appointed as nutritional dviser, first to Central Command, and latterly to Allied Land orces. His work to improve the nutritional status of British and ndian troops constituted an important contribution to the war effort nd earned for him a considerable local reputation. He travelled ontinually and examined approximately 40,000 men in the course of utritional surveys. His personality, especially his modesty and ense of humour, endeared him to those with whom he was ssociated. His death leaves a gap hard to fill and removes a man f great promise.

Previously reported missing at Arnhem, now officially reported ied as prisoner of war.—Capt. John Howard Keesey, R.A.M.C.

Missing, presumed killed.—Temp. Surg. Lieut. Lachlan McLachlan, .N.V.R.

Prisoner of war.—Lieut.-Col. E. Townsend, M.C., R.A.M.C.

Obituary

SIR HENRY GAUVAIN, M.D., M.CH., F.R.C.S.

y the death of Sir Henry John Gauvain the medical profession as lost not only a pioneer and eminent authority on surgical uberculosis and heliotherapy but also a man of remarkable ersonality and charm.

Gauvain was born in Alderney in 1878. He was the son f William Gauvain, and both his parents were descendants f old Alderney families. He was educated privately and ater entered St. John's College, Cambridge, as a scholar. He ad a distinguished career at Cambridge and obtained first-class honours in the Natural Sciences Tripos of 1902. He then went to St. Bartholomew's Hospital as a scholar. After qualifying in 1906 as M.B., B.Ch., and M.R.C.S., L.R.C.P. he became house-surgeon to Mr. C. B. Lockwood, and also held intern and extern obstetric appointments.

In 1908 Sir William Treloar founded the Lord Mayor Treloar Cripples' Home at Alton for children suffering from surgical tuberculosis, and offered Gauvain the post of resident medical officer. Many of Gauvain's friends tried to dissuade him from accepting a post nvolving treatment of a condition for which practically nothing ould be done, but he, being a man of vision, thought otherwise. t that time little was done in this country for children suffering rom bone and joint tuberculosis. Gauvain paid a brief visit o Berck-sur-Mer, where the treatment of these cases by onservative methods had been carried on for about 30 years, nd he started the treatment at Alton on the same lines, odifying and amplifying it in accordance with his own ideas nd experience. In a few years' time Gauvain's work, and the esults obtained, proved the words "Cripples' Home" to be a isnomer, and the title of Lord Mayor Treloar Cripples' ospital was given to the institution, which was acquiring both national and an international reputation, and Gauvain was ppointed medical superintendent.

In view of present-day treatment of bone and joint tuberulosis it is perhaps interesting to refer to some of Gauvain's arly troubles. Many of the members of the honorary medical oard, which was composed of distinguished consulting surgeons nd physicians of the time, were strongly opposed to Gauvain's reatment of tuberculous abscesses by aspiration. They saw o need for an x-ray apparatus, and he also had great difficulty in obtaining their sanction to buy a sterilizer for dressings, as the medical board did not consider sterile dressings to be necessary in tuberculous conditions.

Gauvain's name has always been associated with heliotherapy, and from the time he first started work at Alton he had been interested in the effects of sunlight on his patients, and had successfully demonstrated its value in suitable cases. For many years he was convinced of the value of sea-bathing in conjunction with heliotherapy in properly selected cases, but it was not until it was found possible to open the marine branch at Sandy Point, Hayling Island, in 1920 that the outstanding benefits of this form of treatment could be demonstrated. A few years before this time Gauvain had recognized the need for children at Alton to have some form of education. At first this was given by one or two nurses chosen for the purpose, but later the then Prime Minister, Mr. Lloyd George, on the occasion of a visit to the hospital, was so impressed by the need for educational facilities that the matter was brought before Parliament, and Alton became the first of the hospital schools in this country.

In 1920 Gauvain received the honour of knighthood for his services to cripple children. In 1925 he opened the Morland Clinics for private patients, where it is hoped that the work he started will continue. In 1927 he was elected Fellow of the Royal College of Surgeons, having proceeded to the degrees of M.D., M.Ch. 9 years earlier. For several years before this there had been further increase in the interest taken in light treatment, more especially in artificial light treatment, and Gauvain was one of the leaders in the movement. He paid several visits to the Finsen Institute, where he was elected an honorary member of the Medical Society of Copenhagen. He was always interested in the treatment of lupus, and a relatively large number of such cases were always under treatment in the Light Department at Alton. He held very definite views on the treatment of adult lupus patients and favoured the colony system, with suitable occupational therapy, as opposed to attendance as an out-patient at a hospital or clinic.

In 1926 he went on a lecture tour in the United States and Canada, and in 1936 he was made the recipient of the Distinguished Service Gold Key of the American Congress of Physical Therapy. In 1935 the British Medical Association Meeting was held in Australia, and Gauvain was president of the Section of Tuberculosis and Public Health. He gave the presidential address on sea-bathing in the treatment of surgical tuberculosis, and received the honorary degree of M.D.Melbourne.

About 15 years ago the rebuilding of the hospital at Alton was begun. This gave full scope to Gauvain's interest in hospital design and organization, and the present hospital with its imposing structure and equipment stands as a monument to his work. Following a generous benefaction in 1938 plans were made to build a hydrotherapeutic centre for the treatment of anterior poliomyelitis at the Hayling Island branch. He had always cherished the hope that this would be used for both adults and children of all classes. In 1940 he took under his care at Morland Clinics 100 Belgian children from an orthopaedic hospital evacuated from Ostend. In gratitude for his kindness to them he received a book from the Belgian Government containing letters from the Prime Minister, the Belgian Ambassador, and the President of the Belgian Red Cross.

Gauvain was consulting surgeon in tuberculosis to three county councils and held numerous other consulting appointments; he was also the author of papers on surgical tuberculosis, hospital design, and heliotherapy. But it was perhaps as medical superintendent of the hospital at Alton that he was best known. He was considered by many to be the ideal medical superintendent. He was beloved by his patients and his staff. He chose his staff with care, and if he was convinced of their competence gave them adequate scope, and remained himself unobtrusively but keenly observant of their work. But to those who had worked longest with him and knew him best it was his great-hearted kindliness that so endeared him to them; truly we shall not look upon his like again.

He married in 1913 Louise, daughter of the late William Butler, M.R.C.S., formerly I.M.S., and is survived by her and a daughter who is also a doctor.

CECIL JOLL, M.D., M.S., M.CH., F.R.C.S.

We regret to announce the death on Jan. 25, at the comparatively early age of 60, of Mr. Cecil Joll.

Cecil Augustus Joll was the second son of Mr. F. W. Joll of Bristol, where he was educated at the University College of that city before coming to University College Hospital in London. Alike in the number of his academic distinctions and of the hospitals to which he was attached as surgeon, he exhibited an exuberance which testified to the driving-power of one of the most dynamic surgeons of the generation which is now mostly sexagenarian. He had begun by studying dentistry, and became L.D.S., R.C.S. in 1907. Taking up medical study, in 1909 he was M.B., B.S.Lond., gold medallist with honours in medicine, surgery, pathology, forensic medicine, and hygiene. Gold medals and scholarships were common incidents in a career which included F.R.C.S.Eng. in 1910, M.S.Lond. in 1911, M.Ch.Bristol in 1911, and several other degrees or diplomas from each of these corporations. After qualification he was senior house-surgeon at the Leicester Royal Infirmary, house-physician at the Birmingham General Hospital, and senior R.M.O. at the Royal Free Hospital, London, where he was later for many years on the visiting surgical staff, and, finally, senior surgeon. He was senior surgeon to the Royal Cancer Hospital, London, surgeon to the Victoria Hospital for Children and to the Miller General Hospital; he was also surgeon to seven or eight hospitals in the Home Counties within reasonable distance of London. In the last war he was surgeon-in-chief to the Majestic Hospital in Paris, senior surgeon to the Richmond Military Hospital, surgeon to the Endsleigh Place Hospital for Officers, to the Michie Hospital in Queen's Gate, to the Maxillo-Facial Hospital, and to the Brook Hospital.

[Photo by Lafayette, Ltd.

This imposing catalogue of activity is an index to the man himself. He drove himself and all his subordinates with relentless energy, and was never so happy as when facing an operation list of ten or twelve or fourteen cases—in fact, would grumble at his house-surgeon if confronted with less. He loved to keep two theatres open with a separate theatre staff in each; when he had completed the essentials of one operation he would leave a trusted assistant to do the suturing and immediately start on a case, already anaesthetized, in the other one. As an operator his technique was masterly; never appearing to be in a hurry, he was so purposive that everything looked easy, and his rapidity and dexterity were almost unbelievable. His reputation stood highest, perhaps, in the surgery of the thyroid gland; but he was just as pre-eminent in the technique of gastric surgery; indeed, a visitor from the Antipodes, who had concluded a surgical tour of American and Continental clinics with a visit to London, once said that in gastric surgery Joll was the best operator he had seen. He could, moreover, do extremely well almost everything that comes within the ambit of a general surgeon. Nor was he merely an operating machine; his judgment was excellent, and his estimate of how much of the thyroid gland not to remove was very seldom at fault. No doubt the all-round experience gained in early days, including that of dental surgery, was of value in the make-up of one who came close to Moynihan's description of himself as "a physician who operates." And the end-results of his cases were as satisfactory as the operative technique: he did not operate to show off what he could do with a knife. The confidence of his surgical colleagues was shown by his election to the Council of the R.C.S.

As for the man himself, he touched life at many points. As a collector he had sound taste, and could buy only first-rate stuff. Water colours were a hobby he indulged freely, and he was also knowledgeable in furniture and pottery. He was a notable connoisseur of good food, good wines, and good cigars. He was also a keen ornithologist. He was Hunterian Professor at the Royal College of Surgeons in 1923; and in 1932 he produced his *magnum opus, The Diseases of the Thyroid Gland.* Most, but not all, of his contributions to surgical symposia (and to these columns) dealt with the surgery of this organ. He joined the B.M.A. in 1909, was honorary secretary to the Section of Surgery at the Annual Meeting o 1924, and president of the Section in 1931. His capacity for work was prodigious, and he worked longer hours, almost certainly, than any other surgeon of his time; yet he wa always eager to spend half the night dancing as well, and would then rise at some very early hour of the morning to visit and operate at one of the hospitals outside London to which he was attached. Returning when many men had hardly finished breakfast to carry on his large private practice he would spend the afternoon operating at one or other of his London hospitals till dinner time; and this routine would go on day after day and year after year. He was a phenomenon the like of whom certainly his contemporaries and his junior associates have not met before and are not likely to meet again Joll married first, in 1924, Miss Laura Winsloe of Liverpool she died in 1931, and he married secondly, in 1936, Miss Antonia Ramsden. He had two sons (one by each marriage) who with his second wife survive him; to them a wide circle in the profession and outside it offer their sincere sympathy

---

Major **WILLIAM NAPIER**, M.B., F.R.C.S.I., who had practised for many years at Epsom, has died as the result of enemy action. He was born in Co. Down 50 years ago, and wa educated at Campbell College, Belfast. He broke off hi medical studies at the Queen's University, Belfast, at the beginning of the 1914–18 war and was soon in command of a combatant unit in France. Towards the end of that war he graduated and took the F.R.C.S.I. in 1920. At school and universit he was one of the best forwards in the rugby sides and playe in the Irish Trials. Most of his life was spent in practice at Epsom, where he was deservedly beloved and trusted by his patients and by all the racing fraternity in that town. He was in addition to being a very successful practitioner, a surgeon o no mean ability. He rejoined the R.A.M.C. in the present war William Napier (writes J. C. R.) owes no small portion of h success in life to the sympathy and tender care which h received from his devoted wife. What meant most to him i life was not the plaudits of the world but his friends and his beautiful and perfect family life. "We live in deeds, not years: in feelings, not in figures on a dial. He most lives wh thinks most, feels the noblest, acts the best."

Dr. **CHARLES FRANKLIN PEDLEY**, who died on Jan. 9, was deputy medical officer of health for Bournemouth and hel office as honorary secretary of the Section of Public Healt (including tuberculosis) at the Annual Meeting of the B.M.A at Bournemouth in 1934. He was born in Rangoon on Feb. 1888, son of Thomas Franklin Pedley, M.D., and from Marlborough went to study medicine at Jesus College, Cambridge, where he took his B.A. in the Natural Sciences Tripo He went on to Guy's Hospital for his clinical course and qualified M.R.C.S., L.R.C.P. in 1914. After house appoin ments at Guy's he became in turn assistant resident medic officer at the North Wales Sanatorium, Denbigh, and a Baguley Sanatorium, Manchester, and was then senior R.M.O at Winsley Sanatorium, near Bath. During the last war he was surgeon to a Belgian field hospital. After demobilization and before taking up the appointment at Bournemouth Dr. Pedley was assistant school medical officer under the Birmingham Education Committee. He obtained the D.P.H of Cambridge in 1925.

The late Dr. **JAMES REID DICK**, a former chairman of the Scarborough Division of the B.M.A., studied medicine a Downing College, Cambridge, and the London Hospital. He graduated B.A. with honours in the Natural Sciences Tripo of 1906, M.B., B.Ch. in 1912, and took the F.R.C.S.Ed. in 1919. After qualifying with the English Conjoint diplomas in 1909 he held a number of house appointments at the London Hospital. A colleague writes: "Dick was outstanding in hi loyalty. At whatever hour of the day or night, however bus he was, a call to a patient or to a consultation always had an instant response. At all times he did his utmost and never let a patient or a colleague down. He was an excellent exponent of practical surgery, and his judgment and surgical acumen were equally good. He loved his work at the Scarborough Ho pital, to which he gave devoted service, and much that he d there was unknown and unseen. He knew his limitations in surgery and would often refuse to operate when he thought that others had more experience for that particular case. His work was his main and abiding interest, and nothing was allowed to interfere with it; but after his work his love of golf came very close. His loyalty was unquestioned but never blind, and if he saw a fault he tried hard to remedy it. He had a decisive mind and was not easily persuaded by argument against reason. In medical politics he was most conservative and detested the prospect of political interference in medical freedom. A fine partner, a very true and loyal friend and teacher, has passed on." C. G. G.-W. writes: "For over thirty years, in a happy partnership, Dick revelled in his practice at Scarborough and gained the affection of both patients and friends for his lovable qualities and his exceptional gifts in the profession to which he gave his all until sickness cut him down while yet in his prime. I learnt his worth when serving with him in France and Italy in the first world war, and can vouch for the high standard which he set himself and never ceased to maintain. 'Richard,' as his friends in France styled him, was a glutton for work and his relaxation was golf, at which he excelled. To have twice holed out in two at the long 18th hole at Gauton was a remarkable feat, if not unique. It is especially to those lovable qualities, which endeared him to so many, that I wish to pay a grateful tribute. When his light went out so suddenly an aching void was left in the hearts of his many friends. To his wife and three sons serving in the war our sympathy goes out."

News has reached this country from his pupil, Dr. Aldo Muggia, of Quito, Ecuador, of the death of Prof. BENEDETTO MORPURGO. He was born at Trieste on Aug. 15, 1861, and died in Buenos Aires on Aug. 21, 1944. It was in 1903 that he followed his teacher, Prof. Bizzozzero, in the chair of general pathology at the University of Turin. In the words of our correspondent, Prof. Morpurgo was deeply convinced of the morphological orientation of medical science, and he remained firmly loyal to his principles even when new tendencies began to prevail. His earliest work (1888) was a study of the laws which govern the regeneration of organic cells. With Canalis he began in 1890 experimental tests showing that complete fasting caused the loss of natural immunity against infections. He made many important contributions to the physiology of nerve and muscle, to cellular pathology, and on homoplastic and heteroplastic grafts. On the occasion of the 35th anniversary of his professorship a collection of original papers was offered to him by his disciples and by scientists from various parts of the world; this filled two large volumes, and contained treatises on a number of subjects in physiopathology. Prof. Morpurgo was an associate member of many foreign medical academies and often attended international congresses on general pathology, presenting there the results of his own investigations and those of his pupils. From 1925 to 1938 he directed the Cancer Institute of the City of Turin. After the Fascist Government had interrupted this charitable work its racial laws sent Prof. Morpurgo into exile.

Universities and Colleges

UNIVERSITY OF OXFORD

In Congregation on Jan. 23 the title of professor was formally conferred on Miss Ida Mann, D.Sc.Lond., F.R.C.S.Eng., Fellow of St. Hugh's College and Margaret Ogilvie Reader in Ophthalmology in the University. She is the first woman to receive the title of professor at Oxford. Prof. E. H. T. Liddell said in Congregation that hitherto the University had been making up the small stipend attached to the readership in ophthalmology to £1,000, and this would now be doubled; they were confident that the title of professor would assist Dr. Mann to build up a distinguished staff for her new Department of Ophthalmology.

In a Congregation held on Dec. 23, 1944, the following degrees were conferred:

B.M., B.Ch.—P. B. S. Fowler, L. Parker, R. A. Sladden, P. West, A. H. James, A. E. Preston, Mary R. Barker, Margaret K. Wilder. *In absence.*—R. G. Howell, A. A. Jefferson, D. Leigh, R. M. T. Walker-Brash, G. M. Colson, R. H. Marten, C. J. H. Starey, Joan F. Scott.

UNIVERSITY OF EDINBURGH

At a graduation ceremonial on Jan. 20 the following medical degrees and diplomas were conferred:

M.D.—*†M. E. S. Harrison, *A. S. Johnstone, I. F. Mackenzie, †E. G. L. Mark, †J. M. M. Batheson, lieut.-col., R.A.M.C., *†J. B. Pennybacker, †H. G. Triay.

D.Sc.—Department of Pure Science: J. N. Davidson, M.D.

M.B., Ch.B.—D. F. Aitken, M. M. Andrew, C. Austin, A. D. Bethune, C. G. H. Bourhill, Henrietta M. Brand, R. B. Crombie, G. B. Debenham, T. F. Elias-Jones, I. S. Ferguson, J. C. Foster, M. I. Girdwood, C G. I. Gordon, Vivian M. Guthrie (*née* Duncan), Jessie H. Ingram, D. M. Johns, F. R. C. Johnstone, J. Lister, R. C. W. Lowe, P. S. Lurie, E. M'Ewen, K. M'Lay, J. M'Lelland, W. W. M'Phail, R. Mendick, A. G. Moffoot, †K. S. Mowatt, J. E. Norman, Joyce M. B. Orr, Patricia M. M. O. Paterson, Barbara Petrovskaia, T. Philp, K. H. S. Pottinger, ‡R. F. Robertson, ‡J. S. Robson, P. F. Scott, H. A. E. Simpson, Carol M. S. Spence (*née* Walker), J. T M. Stevenson, J. L. Stewart, B. J. I. S. Sutherland, R. W. Tonkin, J. G. Trimble, J. G. Walker, M. Wiederlight, E. A. M. Wood, A. D. C. Young.

DIPLOMA IN MEDICAL RADIOLOGY.—M. M'Alley, Lesley I. Thomson (*née* Stewart), C. Kelly, Margaret S. King, K. A. Mackenzie.

* Highly commended for thesis. † *In absentia.* ‡ With honours.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

Sir Girling Ball will deliver the Bradshaw Lecture at the College (Lincoln's Inn Fields, W.C.) on Thursday, Feb. 8, at 3 p.m. His subject is "End-results of Treatment of Growths of the Bladder."

The Hunterian Oration on "The Hunterian Museum" will be delivered by Prof. G. Grey Turner at the College on Wednesday, Feb. 14, at 3.30 p.m.

Medical Notes in Parliament

Paper for Medical Books

Major NEVEN-SPENCE asked on Jan. 17 for an increase in the paper quota available to the medical group of publishers in order to counteract the growing decline in the production of medical books. Capt. WATERHOUSE replied that quotas of paper were based on publishers' pre-war usage and did not vary with the types of books they produced. Mr. Dalton, however, had arranged last autumn for a substantial increase in the special reserve for books of particular importance, including medical books, which publishers could not produce from their quotas.

Emergency Medical Service

Mr. LIDDALL suggested on Jan. 18, in view of the fact that throughout the country many people were unaware of the activities of the E.M.S., that Mr. Willink should make a statement on the services that have been and still were being rendered.

Mr. WILLINK answered that aspects of the Emergency Hospital Scheme, commonly known as the Emergency Medical Service, had been described in recent annual reports of his Department, and had also been the subject of many newspaper and magazine articles and broadcasts. The scheme provided treatment not only for the sick and wounded of the Forces and for air-raid casualties but also for many classes of civilian sick and injured. The scheme had also developed such allied services as rehabilitation, blood transfusion, laboratories, and ambulances. There might be an opportunity of reviewing the scheme as a whole on some future occasion such as a debate on the Estimates. He wished to pay tribute now to the hospital authorities and to the medical, nursing, and other staff of the hospitals, who had co-operated so well with his officers in making the scheme a success.

Bethnal Green Shelter Disaster

On Jan. 19 Sir JOHN ANDERSON read in the House of Commons a statement which Mr. Herbert Morrison had prepared about the Bethnal Green shelter disaster. In this Mr. Morrison disclosed that when he directed High Court proceedings to be *in camera* he had before him an opinion, delivered by an experienced metropolitan magistrate after a painstaking inquiry during which 80 witnesses were examined, that the effective cause of the disaster was that a number of people lost their self-control at a particularly unfortunate place and time. He added that the Government decided in April, 1943, that public reference to the psychological cause might be an incitement to the enemy, with the resources then at his disposal, systematically to continue a form of attack which seemed likely to create a considerable disturbance to the life of the Metropolis. There was the added possibility of heavy casualties being caused until structural alterations could be made in the light of experience to many underground shelters.

Foot-and-Mouth Disease

In the House of Commons on Jan. 23 Mr. TURTON raised the question of the continued outbreaks of foot-and-mouth disease. He urged the importance of disinfecting the vehicles which carried imported meat from Argentina before they were used for livestock and feeding stuffs.

Mr. T. WILLIAMS said that if we could concern ourselves with the disease alone, obviously the straightforward method would be to prohibit the import of meat from those countries where foot-and-mouth disease was endemic or outbreaks were known to be occurring. That, however, was almost out of the question. To concern ourselves with disease alone would reduce our meat ration to about 9d. per person a week. Vehicles used for conveying imported meat were also used to convey home-killed meat. He was sure that Parliament would not agree to an Order which required that vehicles used for the distribution of meat should not be used for carrying livestock and should not subsequently be used for carrying other goods until properly cleansed and disinfected. An Order covering the wholesale distribution of meat would cause great dislocation difficulties. Last year (1944) saw a heavy wave of disease in South America, which, if the transport risk had been great, ought naturally to have expressed itself in outbreaks where vehicles had conveyed meat and other goods to and from farms in their daily work. Not one original outbreak in 1944, however, was traced to a vehicle conveying imported meat. Nevertheless no opportunity should be lost of impressing on those who conveyed imported meat the importance of properly cleansing and disinfecting vehicles before carrying livestock. With regard to pigs it was not so much the butcher as meat scraps which were a danger to livestock. If the Orders already in existence were faithfully complied with the danger would be reduced enormously.

Direction of a G.P.—In a reply on Jan. 18 to Sir Arthur Evans, Mr. Ernest Bevin said a doctor in general practice in Cardiff had been found guilty of failing to comply with a direction to take up a post in a hospital, alleging conscientious objections. For this offence the doctor had been convicted and fined, but remained liable to be directed to other suitable employment. Directions would be issued accordingly if and when a post was found for him which was suitable, having regard to his experience, qualifications, and other circumstances.

Bedding and Upholstery Stuffing.—Mr. Hewlett alleged on Jan. 18 that this country was considerably behind other countries in the standard of cleanliness required for the filling of bedding and upholstery and that British importers were being offered objectionable materials.

Mr. Willink answered that the need for a comprehensive review of this subject led in 1938 to the appointment of a Departmental Committee. In view of the importance of the subject arrangements were now being made for the committee to resume its work.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the incidence of measles was less than in the previous week by 968 cases, and that of scarlet fever by 132, while for other diseases the following rises were reported: acute pneumonia 157, whooping-cough 140, dysentery 98, and diphtheria 20. Deaths from influenza in the great towns have increased, the total now being 72; in the previous two weeks they numbered 35 and 55. In the combined regions of London, south-east, south-west, south midland, and eastern, notifications of diphtheria rose from 58 to 102, but for the rest of the country they fell by 24. Acute pneumonia is also prevalent in the south. The only large local variation in whooping-cough was Lancashire—a rise of 47 cases over last week's total. Lancashire reported 307 fewer cases of measles than last week, Nottinghamshire 252, Staffordshire 175, Cheshire 81, and Middlesex 59, but in Yorks West Riding cases mounted by 92, in Yorks North Riding by 78, and in Worcestershire by 69.

In Yorks West Riding notifications of dysentery rose from 13 to 100 (Wakefield C.B. 81, Sheffield C.B. 14). The other large returns were those of London 36, Lancashire 40, Southampton 16 (Petersfield R.D. 12), Buckinghamshire 14 (Aylesbury R.D. 13), Glamorganshire 10 (Cardiff C.B. 9).

A case of smallpox has been confirmed during the week ending Jan. 27 in a military camp in Anglesey. The 1,400 personnel have been vaccinated and placed in quarantine and the civilian population have been offered vaccination facilities.

In *Scotland* rises over last week's total notifications occurred as follows: whooping-cough 201, measles 192, scarlet fever 20, diphtheria 13. Notifications of primary pneumonia fell by 49, and those of dysentery by 28. A new outbreak of dysentery occurred in Clackmannan County, where 14 cases were reported.

In *Eire* the incidence of whooping-cough fell by 22, the totals for the other diseases remaining constant.

In *Northern Ireland* the notifications of measles fell by 42, and those of diphtheria by 7.

Week Ending January 20

The returns of infectious diseases in England and Wales during the week included: scarlet fever 1,564, whooping-cough 1,785, diphtheria 518, measles 12,054, acute pneumonia 1,399, cerebrospinal fever 77, dysentery 377, paratyphoid 1, typhoid 11. Influenza deaths in the large towns totalled 56.

No. 2

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 13.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1945					1944 (Corresponding Week)

* Measles and whooping-cough are not notifiable in Scotland, and the returns are therefore an approximation only.

† Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

‡ Includes puerperal fever for England and Wales and Eire.

§ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Medical News

Dr. Albert Schweitzer, philosopher, theologian, musician, and doctor of medicine, was 70 years old on Jan. 14. In his medical capacity he has run a hospital in French Equatorial Africa for the past 30 years. A *Bulletin* celebrating Schweitzer and his work has been published by the British council for his hospital and is issued from Friends House, Euston Road, London, N.W.1.

A meeting of the Medical Society of the L.C.C. Service will be held at Paddington Hospital, Harrow Road, W., on Wednesday, Feb. 7, at 2.30 p.m., when members of the staff of Paddington and St. Charles' Hospitals will demonstrate cases.

The next quarterly meeting of the Royal Medico-Psychological Association will be held at 11, Chandos Street, W., on Wednesday, Feb. 7, at 10.30 a.m., when discussions on "Electro-encephalography in Relation to Psychiatry" and "The Impulsive Psychopath" will be opened by Dr. Denis Hill and Dr. R. Sessions Hodge respectively, and Mr. W. Grey Walter will speak on "The Analysis of the Fine Structure of the Electro-encephalogram."

A lecture on "The Health Services of the Soviet Union" will be given by Dr. S. A. Sarkisov, professor of neuropathology at the Moscow Institute of the Brain and representative in Great Britain of the Red Cross and Red Crescent of the U.S.S.R., at the Pharmaceutical Society of Great Britain, 17, Bloomsbury Square, W.C., on Thursday, Feb. 8, at 7 p.m. A discussion will follow.

The Association of Scientific Workers has arranged a conference on "Science in Peace." to be held at Caxton Hall, Westminster, on Saturday and Sunday, Feb. 17 and 18. The subjects for discussion are "Science and Production," on Saturday afternoon at 2.15; "The Future Development of Science," on Sunday morning at 10; and "Science and Everyday Life," on Sunday afternoon at 2.30. Tickets, price 5s. (or 2s. 6d. for each of the three sessions) may be had from the A.S.W., Hanover House, 73, High Holborn, W.C.1.

The inaugural meeting of the London and Home Counties Medical Group of the Newman Association will be held in Hereford House on Sunday, Feb. 11, at 5 p.m., when Dr. H. E. Magee will speak on "Science and Life." All Catholic doctors are invited.

The Leverhulme Trustees invite applications for fellowships and grants in aid of research from British-born senior workers prevented by routine duties or pressure of other work from carrying out research. Forms may be had from the secretary, Dr. L. Haden Guest, M.P., Leverhulme Research Fellowships, Unilever House, Blackfrairs, E.C.4. They must be returned by March 1.

The Council of the Royal Society of Medicine has appointed a committee, under the chairmanship of Prof. E. C. Dodds, to investigate the effects of oestrogens in cancer.

Dr. J. R. Peters, senior assistant medical officer of health for the City of Glasgow, will succeed Dr. Thomas Ferguson as deputy chief medical officer of the Department of Health for Scotland. Dr. Ferguson was recently appointed to the chair of public health in Glasgow University in succession to Prof. James M. Mackintosh.

Dr. R. A. Young, consulting physician to the Middlesex and Brompton Hospitals, has been elected vice-chairman of the National Association for the Prevention of Tuberculosis, in the place of Sir Percival Horton-Smith-Hartley, who has retired on grounds of ill-health.

Prof. L. S. P. Davidson, M.D., of Edinburgh University, has accepted the invitation of Harrogate Town Council to investigate the lines of research which should be taken by the Corporation on the internal and external use of the Harrogate waters, the bathing establishments, and the treatments given.

Circular 170/44 issued to local authorities by the Ministry of Health deals with diphtheria prophylaxis. It is accompanied by a brochure on this subject (published by the Ministry of Information for the Ministry of Health and the Central Council for Health Education) which sets out particulars of facilities available for local publicity, with samples of printed material, etc., in a pocket at the back. The Minister feels that the brochure should now be distributed so that local authorities may make their plans for local campaigns in the spring and summer of 1945. Between Jan. 1, 1940, and Dec. 31, 1943, the number of children in England and Wales who, at ages under 15, had been immunized against diphtheria during those years under local authorities' arrangements was over 4,800,000. Of these more than 1,680,000 were children under 5 years of age when immunized. These figures show the widespread response by local authorities and their officers, as well as by doctors, parents, and others, to the call to combat the disease. Normally the best time for immunization is just before the first birthday, because the ensuing years, in which the risk of infection is high, are thus covered from the outset.

Letters, Notes, and Answers

All communications with regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1. TELEPHONE: EUSTON 2111. TELEGRAMS: *Aitiology Westcent; London.* ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Publishing Manager, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager, B.M.A. House, Tavistock Square, London, W.C.1 (hours 9 a.m. to 5 p.m.). TELEPHONE: EUSTON 2111. TELEGRAMS: *Articulate Westcent, London.*

MEMBERS' SUBSCRIPTIONS should be sent to the SECRETARY of the Association. TELEPHONE: EUSTON 2111. TELEGRAMS: *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Brittle Nails

Q.—*A school nurse, 54 years old, has an excellent medical history except for sudden onset of amenorrhoea when 28 years of age. In the past months her nails have become brittle and have receded in some cases to within 1/4 in. of the cuticle. When cut, lateral growth is more rapid than central. She has never used nail varnish. Lysol and dettol are employed in the clinic, but she has used them for years. Her diet is as full as wartime permits.*

A.—In general, diseases of the nails may be divided into three categories: (1) Those caused by general or local infections. The latter refer to ringworm; the fungus may be found in scrapings made from the nail surface. (2) As a part of some general skin disease, such as psoriasis, where nail changes are commonly found. (3) As an idiopathic process in which, as a rule, the normal nail growth is gradually re-established under treatment. The case in question seems to belong to the third category, but ringworm infection should of course be excluded. If this has been done, treatment consists of giving arsenic by the mouth and small doses of *x* rays to the nail.

Phlebitis Migrans

Q.—*What is migratory or ambulant phlebitis, its cause and treatment? A patient suddenly, without apparent cause, starts phlebitis in the right saphenous vein, in Scarpa's triangle, an inch or two below its junction with the femoral. A few days later this apparently clears up, and a patch of inflamed saphenous vein appears in the inner side of the leg. Shortly afterwards the saphenous vein on the other side becomes similarly affected and behaves in a similar manner. One area improves as another becomes affected. This particular patient has never had veins affected elsewhere. May I have suggestions on treatment and relief of this distressing and disturbing complaint?*

A.—Migratory or ambulant phlebitis is a big subject. It would be helpful to know the age and sex of the patient. The fact that the trouble is confined to the legs suggests that the veins here are diseased—? varicose, ? compensatory to old phlegmasia alba dolens. The patient may have had a previous prolonged infectious condition like typhoid, peritonitis, or puerperal fever. A septic focus elsewhere will cause the infective condition in the diseased vessels. Blood diseases, such as a marked ordinary anaemia, pernicious anaemia, acholuric familial jaundice, must be excluded, as well as syphilis, gout, diabetes, low blood pressure, and nutritional debility. Occasionally subacute rheumatism is present, or the migratory phlebitis may be a manifestation of thrombo-angiitis obliterans, usually in males who smoke excessively. Should the patient be a female, then an abdominal tumour must be excluded as well as a urinary infection; to a much less extent this applies to the male. Rarely phlebitis migrans announces an undetected malignant disease in the stomach in the male, and in the uterus or cervix in the female. Thus a complete blood examination is essential. The common septic foci should be searched for—e.g., the nasal sinuses, the teeth (dead ones should be extracted without hesitation), the tonsils (a previous quinsy is a direct indication for tonsillectomy, as are tonsillar remnants), the gall-bladder, appendix, prostate, and cervix. (While the investigation is taking place, the tendency to clotting can be discouraged by injections or dicoumarol, if the attacks are inconveniently frequent.)

For treatment: if the veins are varicose, ligature and injection at the groin and ankle will settle the trouble. If the veins are not varicose, firm bandages (elastoplast if tolerated) will relieve the discomfort and discourage the phlebitis. During the painful and pyrexial stage the patient should rest in bed for two weeks, with the application of glycerin and belladonna t.d.s. and firm bandages; getting up for toilet purposes is permissible. If there is a smart pyrexia or rigors, then a blood culture should be taken during the exacerbation of temperature, and sulphathiazole (and possibly penicillin) may be needed. When the infected element is pronounced, there is, as your inquirer remarks, the danger of embolism. Reading aloud (unconscious breathing exercises) and gentle purposeful exercises are of assistance in keeping the circulation reasonably brisk, assisting repair, and discouraging further stasis and thrombosis. By mouth, an anticoagulant mixture such as pot. cit., gr. 20 to 30, spirit. ammon. aromat., minims 10 to 20, ammon. carb., gr. 3 to 6, glycerin, minims 20, aqua to 1/2 oz. given four-hourly by day and night is helpful. The diet must be well balanced.

Some American authorities advise the prompt ligature and injection of the termination of the internal saphenous vein at the saphenous opening; not only does it eliminate the danger of embolism, but also it cuts short the length of illness. This requires an expert opinion and technique, and the need to eliminate septic foci still remains.

Subacute Combined Degeneration of Cord

Q.—*What is the latest treatment for subacute combined degeneration of the cord associated with almost complete achlorhydria?*

A.—In subacute combined degeneration of the cord one would expect the achlorhydria to be complete, and the presence of free HCl even in small amounts would cast doubt on the diagnosis. An answer on prognosis and treatment was published on Aug. 7, 1943 (p. 190), and there is little fresh to add. In the early stages of treatment a full dose of liver extract—e.g., 4 c.cm. of one of the ordinary intramuscular extracts—should be injected three times a week. After a month or six weeks the number of injections may be reduced to one a week, but this should be continued for two or three years and only then reduced to one every three weeks. Treatment of this intensity should maintain the red cells above 5 million per c.mm.; if it does not, it should be supplemented by desiccated stomach or proteolysed liver by mouth, half an ounce t.d.s. If haemoglobin regeneration lags behind the red cells iron may be given—e.g., ferrous sulphate gr. 3, t.d.s., p.c. Vitamins B and C are advocated in some quarters, but are unnecessary if the patient is taking a good mixed diet. Physiotherapy is of value in severe cases, particularly re-education and persuasion to do more.

Faecoliths after Cholecystectomy

Q.—*A female aged 50 had a cholecystectomy 3 years ago. She has since complained of intermittent attacks of diarrhoea. During a recent attack she passed about ten stones, on which the pathologist's report is: "Reddish-brown stones weighing from 0.9 to 0.5 g., not easily crushed; small black portions visible when crushed; very little organic matter present; apparently a trace of fat only; consist almost entirely of ferric oxide (haematite), with some sulphide and traces of phosphate and calcium. Analysis: 69.7% iron (ferric oxide contains 69.9% iron)." She has been having no medicine containing iron, but admits to taking pure cod-liver oil for long periods. What might be the nature of the stones, the possibility of their being manufactured in the bowel, and the process by which they might be made?*

A.—Faecoliths are usually composed of calcium salts. It is hardly conceivable that amounts of iron of this order should be derived from the blood or tissues. It is little more credible that they should come from the food. The ferric oxide calculi are probably formed from ferric hydroxide, and a considerable amount of inorganic iron would seem to be necessary to produce this material in such quantity and purity. As the trouble followed a cholecystectomy, one's first thought would be that an instrument had been left behind and found its way into the bowel. Otherwise one would suspect that an inorganic preparation of iron was being taken by mouth. In any event the patient should be examined by x rays. A plain film should be taken, and if this does not solve the mystery a barium meal should be given in case there is a diverticulum in which ingested iron is accumulating.

Chronic Mastitis and Cancer

Q.—*Is chronic mastitis precancerous? Can you quote facts and figures to prove it? Should young women of 30 to 35 sacrifice both breasts, the scar of chronic mastitis, or should they remain under supervision? Is it ever cured, and by what means?*

A.—This collection of questions cannot be properly answered without defining chronic mastitis. Unfortunately the term is applied clinically to a variety of pathological states, including abnormal activity or involution determined by hormones, retention cysts, and the peculiar epithelial hyperplasia the relation of which to cancer was worked out by Cheatle. Of these, the last, a comparatively uncommon condition, is the only one which clearly leads up to carcinoma. Though it would be wrong to suppose that this is in fact the only link between mastitis and neoplasia, it is equally misleading to make the sweeping statement that chronic mastitis, in all its forms, is precancerous. There is no statistical proof that carcinoma occurs with greater frequency in breasts affected by chronic mastitis than in "normal" breasts. The only justification for mastectomy for chronic mastitis in young women is the persistence of pain and disease in the breast in spite of adequate conservative treatment, in the presence of a strong family history of carcinoma of the breast. Conservative treatment should include, first, attention to the general bodily and mental health; secondly, the administration of hormones in suitable cases; and also exposure to small doses of x rays, which may modify, without destroying, epithelial activity in the breast.

Angina and Coronary Occlusion

Q.—*At necropsy on a case of angina pectoris there is always found some degree of coronary sclerosis or occlusion. It would seem, therefore, that coronary occlusion is merely a more advanced (morbidly) state of angina pectoris. In fact it is taught that if angina pectoris pain persists over 15 minutes occlusion is probably present. Why is it, then, that nitrites are recommended for cases of angina pectoris but contraindicated in occlusion? Is one to infer that in the latter the general blood pressure is so low that a further lowering would endanger life? Is it not more logical to argue: (1) blood pressure in the first part of the aorta is always high enough to ensure that blood will flow through whatever part of the coronary circulation is still patent; (2) by lessening peripheral pressure we lessen the work of a heart only part of which is now functioning—and so—give nitrites? Would not the most rational treatment in occlusion appear to be to lay patient flat on back with the foot of the bed raised, and give nitrites (with, of course, morphine for pain)?*

A.—Nitrites relieve the pain of angina of effort, but do not relieve the pain of coronary occlusion. Naturally it is undesirable to lower still further the diminished blood pressure following coronary occlusion. The lowered pressure in the aorta probably renders the coronary circulation less efficient, and a drop in blood pressure is associated with a rise in rate, which increases the work of the heart. If shock and lowered blood pressure predominate the patient should lie flat, but dyspnoea and heart failure may make it necessary for him to sit up.

Unsatisfactory Marriage and Dipsomania

Q.—*How should I advise a husband aged 67 about his wife, aged 44, who is suffering from alcoholism associated with early menopausal symptoms? She has obviously developed a complex, since conjugal frigidity developed 11 years ago when their last child, a son, was born. The husband has since then developed a state which has now become one of complete sterility in spite of treatment. What form of "treatment" should be adopted in order to break his wife of the dipsomaniacal state?*

A.—This is a complex case deserving a treatise. I can only suggest the most probable causes and treatment. The most likely cause of the wife's frigidity is a fear, not necessarily conscious, of getting another child; or she may have ceased to be in love with her husband from that date. It is not surprising, considering his age and her frigidity and lack of response, that he should become progressively impotent. Alcoholism in this case (as in all such cases) is usually an escape from her problem, internal and external; and is most commonly due to frustration. This may have to do with subconscious frustration from her frigidity and her inability to respond. But a great deal of what is put down to sexual frustration is really due to the feeling of lack of affection, especially in a woman, who, more than a man, desires to be loved. At the menopause especially a woman feels that her attraction is going, that her husband will not love her any more, which in this case is accentuated by her frigidity and her husband's consequent sterility Since sex is the symbol of love she would be confirmed in her idea that she was no longer loved. She takes to alcohol as an escape. If such is the situation the husband would be well-advised to give her a great deal more affection and even "fussing," quite apart from sex, to encourage in her the feeling that she is still "wanted"; and she would then have less desire to escape to alcohol.

This, however, is suggested only as a "first-aid" measure, and deals only with probable precipitating causes; but her alcoholism may be due to much deeper emotional disturbances. For instance, she may have married the older husband as a father substitute, and in the course of time grown out of this and now feels thwarted of a husband more her own age. In any case both her frigidity and her alcoholism, as well as desire to escape from life, are probably a regression to an infantile attitude of mind. Even so the demonstration of affection I suggest would not come amiss.

Chloroform in Midwifery

Q.—*I have used chloroform as an anaesthetic in upwards of 5,000 maternity cases, and have never seen any ill effects; but a great deal of discussion has taken place on its use in these cases, and I should be glad of an expert opinion.*

A.—The normal parturient woman stands all anaesthetics extremely well. Her mental approach is good and she welcomes the anaesthetist. Light anaesthesia suffices for the job; in fact, deep general anaesthesia is contraindicated, since it abolishes uterine contractions. The toxic effect of chloroform in these cases is negligible. In the toxaemias of pregnancy or in dehydration from prolonged vomiting the additive effects of even a little chloroform may gravely influence the existing liver dysfunction. In cases of obstructed labour anaesthesia may be prolonged and the cumulative effect of chloroform harmful. It is in institutions to which labour complications are sent that the ill effects, sometimes mortal effects, are seen. Chloroform is excellent in the straightforward case, but should be banned when complications exist.

Sterility after X-ray Therapy

Q.—*How long after the onset of an artificial menopause induced by x-ray or radium therapy may permanent sterility be assumed; and after how long a period of amenorrhoea occurring as a side-effect of x-ray or radium therapy may recovery of ovarian function be hoped for?*

A.—Permanent sterility cannot be assumed for certain after the induction of an artificial menopause with x-ray or radium therapy until three months after the completion of treatment. Patients should be warned of this, as the occurrence of pregnancy after a menopausal dose of radiotherapy is highly undesirable. After an artificial menopause it is usual for one, two, or occasionally three periods to occur, and these may be unusually heavy.

No definite answer can be given to the second part of the question, since so many factors are involved. These include the age of the patient, the dosage employed, and the amount of irradiation delivered to the ovaries. There is also considerable individual variation in the reaction of the ovaries to irradiation.

? Glomus Tumour

Q.—*A married woman aged 30, with one child aged 8, has suffered intermittently for the past 7 years with paroxysmal pain in the left leg over the internal malleolus. Formerly the attacks occurred at intervals of 4 to 6 months, but recently they have become more frequent. The patient describes the pain as "lightning" and as sometimes "shooting" along the tibia towards the knee-joint. When severe it causes her to sweat and vomit and leaves an ecchymosis over the internal malleolus. What are the diagnosis and treatment?*

A.—It is assumed that careful examination of the nervous system has revealed no evidence of organic disease in the region of the 4th lumbar segment of the cord or the saphenous nerve. Lightning pains always suggest tabes dorsalis, which in this patient would presumably be of the congenital variety. If these possibilities have been excluded, the most likely diagnosis is a glomus tumour or angioneuromyoma in the skin or subcutaneous tissue of the ankle. For a brief review of glomus tumours see the article by C. M. Ottley (*Brit. J. Surg.*, 1942, **29**, 387). Fifteen cases were well described by A. C. Lendrum and W. A. Mackey in the *B.M.J.* of Sept. 30, 1939 (p. 676), and the subject was commented on in an annotation in the same issue. Glomus tumours are liable to bleed if knocked or injured. Although they are often small, it should be possible to palpate the tumour, which is characteristically painful. The appropriate treatment is excision.

Penicillin for Syphilis

Q.—*Is there any evidence, and if so what, to demonstrate that Spirochaeta pallida is susceptible to the action of penicillin "in vitro"? How has the present recommended dosage of 2,400,000 units of penicillin for a case of early syphilis been arrived at? Has any literature been published on the treatment of early syphilis with penicillin?*

A.—The cultivation of *T. pallidum* is technically so difficult that proof of its susceptibility to penicillin by *in vitro* test is almost impracticable. The experimental basis for the present clinical study was the demonstration of the efficacy of penicillin in the treatment of syphilis in the rabbit. The present scale of dosage has been determined by clinical experiment. The lower the total dose (below 1,200,000 units, the largest amount used in the only extensive series hitherto published) the more frequently did serological tests become positive again some months after treatment. The original reports on these studies (*J. Amer. med. Ass.*, 1944, **126**, 63, 67, 73) were reviewed in a recent leading article in this *Journal* (Dec. 23, 1944, p. 821).

Goat's Milk for Infants

Q.—*What is the correct method of modifying goat's milk for feeding normal infants?*

A.—The composition of goat's milk is stated to be somewhat variable, but average figures show that the totals of the main constituents (protein, fat, and sugar) are essentially the same as those in cow's milk. Moreover, the amounts of caseinogen and of lactalbumin are also similar, and both milks have the same caloric value of 20 per ounce. It therefore follows that goat's milk should be modified exactly as cow's milk is modified. There is one variation, however, if it is desired to produce anything resembling breast milk—namely, that cow's milk cream must obviously not be used as an addition; instead, one of the synthetic fat emulsions should be used. But, in general, modern paediatric practice is not in favour of "humanized" milk mixtures. Therefore simple dilutions (2, 3, or 4 of milk to 1 of water) with addition of sugar are to be recommended. Dried goat's milk is also available and corresponds in composition to full-cream dried cow's milk. To sum up, goat's milk can be used exactly as cow's milk is used.

Attacks of Cyanosis and Giddiness

Q.—*A childless married woman aged 36 noticed 3 years ago, on movement of the arms or on bending, some blueness of the face, neck, and upper chest, with giddiness and black-outs—the latter particularly after stooping. Menstruation regular but scanty. Diagnosis of goitre has been made. X-ray examination of thorax shows nothing abnormal. E.C.G. shows slight tendency of the electrical axis of the heart to lie transversely, and negative T and P waves in Lead III. Blood pressure variable between 140/104 and 130/100. Arm band of sphygmomanometer causes slight cyanosis of arm. I should like help with prognosis and treatment. The patient is excitable, and when worried her face becomes puffy, but the blueness and distress come on only through exertion.*

A.—One would be chary about attributing this particular group of symptoms to a mental or functional disturbance, particularly in the absence of any history indicating that the attacks have a psychological cause or meaning. Evidence of venous obstruction from thrombosis of the superior vena cava or constrictive pericarditis should be looked for. Carotid-sinus syncope is another possibility, and the neck should be examined with the patient sitting to see if the carotid reflex is over-active. If no mental or psychological cause can be found, the patient should be given a favourable prognosis and treated by sedation with phenobarbitone gr. 1/2 to 1 b.d. Digitalis should be strictly avoided.

Hypervitaminosis D

Q.—*Is there any real danger of hypervitaminosis D? If I take large doses of vitamins A and D (5,400 i.u. of vitamin D per day), I seem able to do my work better.*

A.—There is a real danger of hypervitaminosis D. The symptoms of toxicity are an initial feeling of well-being and good appetite, followed by loss of appetite, nausea, vomiting, diarrhoea, frequency of urination, depression, headaches, sweating, and "pins and needles." Five deaths due to overdosage with vitamin D have been reported in the literature. Necropsy showed calcification of the arteries, cardiac muscle, kidneys, bronchi, and stomach. Excessive doses of vitamin D mobilize calcium and phosphorus so that soft tissues tend to become calcified. Massive single doses appear to do no harm, but the continual use of large doses produces toxic effects. It is difficult to state the dose which will produce toxic effects if taken continuously, as personal sensitiveness seems to vary. 10,000 i.u. per lb. of body weight is stated to be toxic, although doses as low as 500 i.u. per lb. of body weight have produced toxic effects, and even 200 i.u. per lb. is said to have resulted in the death of a child. In an adult 5,400 i.u. daily is unlikely to do any harm, although there is no point in taking such a large dose. 1,000 i.u. daily is ample even in pregnancy and lactation.

INCOME TAX

Assistant formerly Resident in Eire

H. O. has been employed in England as an assistant for the past six months, having come to this country from Eire in May, 1944. Is he liable to deduction of tax under the "pay-as-you-earn" system?

⁂ Yes; his salary as an assistant ranks as an emolument assessable under the rules of Schedule E, and therefore is brought within the "pay-as-you-earn" system.

Part Use of Residence for Professional Purposes

F. G. is in general practice and has a surgery about half a mile from his residence. The residence "is used quite a lot for professional purposes"—e.g., emergency cases outside surgery hours, other cases by appointment, etc. Hitherto a deduction has been allowed representing roughly half the cost of running the residence, and the inspector of taxes proposes to reduce the allowance drastically.

⁂ The deductions in the past have represented almost the maximum allowance made when the main surgery is on the residential premises and seems clearly to have been excessive. On the other hand, it may be that the new basis suggested (1/6th of rent, rates, etc., and £50 for part cost of domestic service) is not adequate—it depends on the actual facts of the case. We cannot advise our correspondent to carry his objection to an appeal to the Commissioners, but personal discussion with the inspector might induce him to make some increase in the deduction he proposes—e.g., 1/4th instead of 1/6th.

Payments for "Sickness Insurance"

"Pi" has in the past treated payments for insurance against illness as professional expenses. The inspector proposes to refuse the deductions in future and to correct past assessments.

*** Such payments are not properly regarded as "wholly and exclusively . . . expended for the purposes of the . . . profession;" neither do they rank for the special "Life Insurance" relief. The inspector is therefore acting within his rights. On the other hand, sums *received* in respect of the insurance are not taxable—but "Pi" has not received any such benefits in recent years.

Assistant: Whether Expense Allowable

M. M., a married woman, is employed as an assistant. If a plate is put up outside her residence, "By Appointment Only," would that justify her in claiming as an expense part of the remuneration payable to her housekeeper? There is one child to be considered.

*** M. M. would have to establish that the expense was incurred "solely, exclusively, and necessarily" in the performance of her duties—including the fact that her contract of employment necessitated her seeing patients at her residence. If that can be established, she would be entitled to deduct some part of the housekeeper's remuneration—probably determined by a proportion of the whole-time spent on dealing with callers.

LETTERS, NOTES, ETC.

Flea-bites and Ingrowing Toenails

Dr. E. Hayling Coleman (Wolverhampton) writes: I am very interested in the query about flea-bites in the *Journal* of Oct. 14, p. 520. I much sympathize with the sufferer, for I have "been there." Before the rebuilding of our out-patient department I rarely came home from out-patients without one of these pests; also after attending medical examinations of recruits during the last war. They raised large urticarial wheals over considerable areas. After trying many things I found a panacea—powdered flowers of sulphur sprinkled inside my underclothing.

With regard to ingrowing toenails, I would mention a simple remedy, usually effective. Pack some powdered lead nitrate down between the side of the nail and the skin. Cover with adhesive plaster to keep it in place. In a few days scrape away the dead skin and re-pack. Usually a few applications effect a cure. Of course the sides of the nail should not be cut beyond the level of the toe. Another method is to cut a V from the *side* of the nail. This takes 20 minutes or more and needs care, but it should cause no pain and is usually very successful. The V. is about 1/8 in. wide at the bottom, tapering slowly upwards nearly to the root of the nail. Both these methods are simple and do not take much time.

Promotion in P.O.W. Camps

"Repatriate" writes: The paragraph bearing this title in "Medical Notes in Parliament" (Jan. 13, p. 65) gives a completely erroneous impression. The only promotion applicable to officers of the R.A.M.C. and A.D.C. is that of lieutenant to captain, and a large number held the latter rank before captivity. The statement hinges on the use of the word "normal." Surely the conditions are most "abnormal," and the position of M.O.'s, dental officers, and chaplains is so vastly different from other officer prisoners of war as to justify abnormal opportunities for promotion being instituted. A statement of this kind only illustrates official disinterest or ignorance of the work M.O.s and D.O.s are doing in captivity.

Translation, Please

Dr. James Burnet (Edinburgh) writes: The difficulty encountered in translating the words "anthrax" and "carbuncle" is due to the fact that in some languages the same word is used indifferently for both conditions. The following notes may prove helpful to your correspondent (Jan. 13, p. 70):

Anthrax.—French: *pustule maligne* (also *anthrax*). Spanish: *ántrax*. German: *Milzbrand* (malignant pustule); *Milzbrandfieber* (the disease itself). Italian: *antrace*.

Carbuncle.—French: *charbon.* Spanish: *carbunclo.* German: *Karbunkel.* This word is sometimes used for "malignant pustule," but the Hun distinguishes "*Karbunkel bösartiger*" (malignant pustule) and *K. gutartiger* (carbuncle). Italian: *carbonchio.*

Pethidine for Asthma

Dr. J. Hepburn (Bedfont) writes: As one who for the past 7 months has personally used pethidine as a help for asthma, perhaps my observations may be of interest. I started with 25 mg. by injection at night—increased soon to 50 mg.; I did this mainly to secure a night's sleep. I soon found that it was a nerve sedative and for various reasons I took extra doses, and now have an average daily amount of 300 mg. Small doses of 25 or 35 mg. act promptly and efficaciously in the morning, and the effects—sedative and antispasmodic—last usually for 4 to 5 hours. Thereafter, 35 or 50 mg. are necessary at more frequent intervals to procure the same results. I have experimented with different amounts and have taken 100 mg. at a dose without deleterious effects. With these bigger doses there is an accentuation of the heart beats and an evanescent light-headedness which soon wear off. I think it unlikely that poisonous doses can be achieved for the simple reason that the atropine-like factor inherent in the composition makes the mouth and throat so dry that further medication is repulsive.

The general claims made on behalf of pethidine are generally correct so far as obstetric, post-operative, and chronic painful conditions are concerned; especially in prostatic enlargement with nocturnal frequency I find it, in doses of 75 to 100 mg., excellent, and the dose need not be increased. There is no doubt that habit formation is more likely if administered parenterally than if taken in tablet form. As regards asthma and tracheitis and mild bronchial catarrh, it certainly is of great help, especially when, as in my own case when holidays and rest are impossible, work has to be done in spite of the infirmity. The larger doses of 100 to 150 mg. certainly give a transient feeling of euphoria, and the inclination is always there to resort to the larger dosage in times of excessive stress and mental and physical strain. It is difficult for me to understand how the symptoms of Dr. Bedo Hobbs's case (Sept. 2, p. 328) can be attributed solely to the pethidine. This drug is rapidly destroyed in the liver and is non-cumulative. The doses his patient took—400 mg. daily for 3 days—should only have had the effect of inducing sleep. Much larger doses have been given—650 mg. in 24 hours—and I myself have taken 400 mg. daily with only the effect of drowsiness and a very dry mouth and pharynx. Still, I do feel that patients may be inclined to take too much, and addiction is a sequela which should be guarded against.

In the treatment of asthma, if addiction be observed, it should be insisted upon that the dose should be kept to the minimum amount which gives relief and comfort; also the oral route should be used. I do not yet know if, in time, it will effect a cure, by virtue of its sedative effect on the central nervous system and its relaxation effects on the unstriped muscle of the bronchi, with, of course, the atropine-like effect of limiting and drying up nasal and bronchial secretions. But, having tried everything already known for asthma and finding that adrenaline causes disturbing cardiac and nervous effects—tremors, etc.—I feel that pethidine is of definite use in cases of asthma which have a psychological factor, and which are associated with bronchial and upper respiratory tract catarrh. I find also that cigarette smoking, whether from the mechanical irritation of the mucosae or from the absorption of the pyridine substances in the smoke, is a deterrent to the best results of the administration of the drug. The drowsy effects from a large dose do not last long, and I have on several occasions had to go to an emergency call in the middle of the night and found no difficulty in collecting all my faculties and in being mentally efficient. Definitely pethidine has its place in the treatment of asthma—especially of the type I have described—but its effects should be watched and regulated.

The Albino and the Swallow

S. W. S. writes under this heading: So far as it was possible to know, the two being related were yet unrelated. The elder of the two sons of a family, full brothers, both albinos, was the more devoid of pigment: his hair was white, his eyes pink; he had a constant nystagmus and a rapid nictitation, and was of somewhat subnormal mental calibre, being withal a silent man. His age was 30 when I first saw him: he was a cellarman, his day's work being carried on under artificial light, well away from sunlight. This albino had found this habit worth cultivating, because thereby he enjoyed the privilege of drinking without paying. In return for a free bottle of ale he could perform thuswise: he stood at the edge of a circle of awed admirers, bent his head backwards till mouth and gullet were aligned, then with the bottle-neck to his mouth, tilted the full bottle upright and swallowed the contents without once going through the act of deglutition. His pomum adami, in its immobility, was watched intently by the onlookers to confirm the fact. At decent intervals this profitable trick was repeated—as often as the generosity of others would extend to the necessary pint, or even quart, of ale. The performance seemed worthier of applause than sword-swallowing. Is the habit one that can be acquired? It is certainly an excessively rare accomplishment. I ask the question, of course, not to emulate, but purely out of curiosity, and mention the instance from greater interest after coming across some reference to the practice in the Acharnians (Aristophanes) in the admirable Hookham Frere translation: "I quaffed it off within my breath; I gulped it in a guggle." A footnote there makes reference to this as "drinking without deglutition; still practised in Catalonia—the Thracian Amystis."

THE MEDICAL CORPS IN RED ARMY OPERATIONS

ITS TASKS AND THEIR FULFILMENT

BY

Prof. YEFIM SMIRNOV

Colonel-General of the Red Army Medical Corps

In the fighting against the German invaders the Medical Corps of the Red Army has played an important part. The enormous scope of the operations which began suddenly in June, 1941, along a front stretching from the Barents Sea to the Black Sea made large-scale organization in the Medical Corps essential: during the period of intensive fighting on the defence the necessary units—field, army base, and front hospitals, clearing stations, and anti-epidemic institutions—were formed and equipped; an extensive network of medical institutions was organized in the rear areas; and doctors—especially surgeons—were allotted posts in accordance with their specialties. The large number of medical workers who entered the Army had to be trained in the problems of war medicine, in the methods employed in dressing and clearing stations, and in anti-epidemic technique during the course of military operations.

The Objective

In this war the Red Army Medical Corps has been and still is faced with quite concrete tasks which entail the employment of the latest ideas in war medicine. These tasks are as follows: (1) To return the maximum number of wounded to the ranks. (2) To reduce to a minimum the cases of mortality among sick and wounded at all stages of evacuation. (3) To reduce to a minimum disablement among those wounded in battle; to ensure that the maximum number of wounded retain their ability to work when their injuries prevent further service in the Red Army. (4) To prevent the spread of epidemics among the troops.

The personnel establishment of the Medical Corps, the tactics adopted under various war conditions, and the equipment and training of the personnel were all directed towards fulfilling these tasks as efficiently as possible. Success in this respect has only been possible because the Red Army Medical Corps works in accordance with a simple doctrine of war medicine under field conditions. In the main this doctrine is based on the following principles: (*a*) A uniform conception of the origin, development, and progress of diseases, and of the principles of surgical and therapeutical work in the field. (*b*) Correct sequence in the treatment of sick and wounded at various stages during their evacuation. (*c*) The obligatory employment of brief, accurate, and consistent medical documents, enabling the sick and wounded to be classified in a thorough manner and their treatment to be uniform at all stages of evacuation. (*d*) A single school of thought, with uniformity in methods of prophylaxis and treatment of sick and wounded at the various stages of evacuation. This school must be based on all that is best in modern medical science, both in the theoretical and in the practical sphere.

In modern warfare the work of the surgeons and its organization are of the utmost importance in the fulfilment of the tasks with which the Medical Corps is faced. The experience gained in war medicine during the 20th century has shown that all gunshot wounds are primarily infected. Naturally the most reliable method of combating the infection of wounds is by early primary treatment. A large number of wounded need early surgical measures, and the best results are obtained when wounds are treated within a few hours of their infliction. This fact to a very considerable extent determines the organization and tactics of the Medical Corps in the field under various war conditions.

To ensure that gunshot wounds are treated surgically as soon as possible we have organized our field units in such a way that the wounded are removed from the battlefield even under enemy small-arm and mortar fire and given skilled surgical treatment in the field medical units. This procedure is dictated by two considerations: first, mortality among wounded in the forward area is most often due to loss of blood; and, secondly, in the army and forward base zones gunshot wounds are complicated by gas gangrene, sepsis, and shock. The chief task of the forward medical units, therefore, is to combat serious loss of blood and to give prophylactic treatment against complication of wounds. For those categories of wounded who require specialized treatment (wounds of skull, eyes, jaws, thorax, the principal long bones, and the larger joints) the Red Army Medical Corps has arranged for this to be given in all institutions, beginning with the mobile field hospitals operating in the zone of the army base. The treatment and evacuation of the slightly wounded and of medical cases are dealt with separately, beginning with the forward units. Mobile therapeutic field hospitals and mobile field hospitals for the slightly wounded are a component part of the medical service of the army in the field.

Principles of Treatment and Evacuation of Wounded

In general, the treatment of wounded in the Red Army is based on a system which deals with each stage of evacuation to a definite destination. This system consists in dividing treatment into a number of stages, without the establishment of specialized hospitals and departments. At each stage the wounded are treated by specialists, and at the same time are evacuated into rear areas of the country. Evacuation is not carried out mechanically from stage to stage, but depends on the type of wound and the condition of the evacuee and also on conditions at the front. Treatment given at the stages of evacuation is consistent and consecutive, progressing in scope and method as the distance from the forward medical stations increases. It is very important to stress the fact that the scope and methods of treatment, the organization, and the speed of evacuation are determined more by the military situation than by purely medical considerations. The following points have therefore to be taken into consideration: the type of operation in which the troops are engaged; the number and the rate of arrival of sick and wounded; the number of qualified doctors, especially surgeons, available at a given stage in evacuation; the availability of transport and the presence, quality, and length of metalled roads; the availability of premises for the accommodation of sick and wounded; the supply of stores and special equipment (surgical instruments, plaster-of-Paris, *x*-ray outfits, etc.); the season of the year and the state of the weather.

To carry out this system of treatment by stages during evacuation to a known destination it is not only necessary to maintain sufficient medical personnel, to render first aid, to give regular treatment, and to evacuate the wounded, but also efficiently to organize and control medical service, especially in the field. The removal of the wounded from the battlefield, the application of first aid, and primary treatment by a doctor are carried out by the forward field units of the Medical Corps, while qualified surgical treatment begins at the casualty clearing stations of army formations in the mobile field hospitals. The evacuation of sick and wounded, starting with the divisional casualty clearing stations, takes place through the medical units of army formations, on warrants issued by them. The slightly wounded that can be treated at the army base go immediately to special local hospitals; wounded needing specialized treatment are dispatched to field surgical hospitals; the sick go to therapeutic hospitals. Patients suffering from infectious diseases are isolated as soon as the diseases become known, and measures are at once taken to prevent spread of the infection; the isolated patients are then evacuated to special mobile field isolation hospitals. The system of evacuation of sick and wounded to a definite destination for qualified specialized attention provides the best possible conditions for their treatment and all the prerequisites for a rapid and complete recovery; it is at the same time a reliable means of combating mortality at all stages of evacuation, and greatly reduces later incapacitation from wounds.

The treatment of wounded at the various stages of evacuation can be carried out only when the medical service is well organized and equipped. An important factor in this respect is the correct distribution of available beds among field, base, and rear hospitals, due attention of course being paid to specialization within each zone. Our war experience has taught us that the number of hospital beds in field, base, and rear-area hospitals depends directly on the nature of operations and the general situation at the front. During the first phase of the war, for example, when our troops were withdrawing under enemy pressure, the situation demanded that the minimum number of beds be retained in the field and base hospitals. When the Red Army assumed the offensive and the rate of advance to the west quickened, it became necessary not only to make a great increase in the number of beds in field and army base hospitals but also greatly to augment the number of hospital units in these areas.

In carrying out the treatment and evacuation of wounded there are four main points on which success or failure of the system depends. First, the correct diagnosis of wounds and the proper classification of wounded at all stages of evacuation; secondly, the presence of a network of specialized hospitals at army bases and their correct clearing in the general directions of evacuation; thirdly, precision work on the part of transport and the organization of clearing centres, which ensure the rapid dispatch of wounded to the next stage; fourthly, the manœuvring of available hospitals, transport, and reserves in accordance with changes in the military or medical situation.

Principles of Organization of Anti-epidemic Work

Experience has shown that in all wars infectious diseases are a serious danger to troops in the field. The Red Army Medical Corps therefore employs a carefully planned system of anti-epidemic measures. Among the prophylactic measures adopted the most important are: constant strict medical control regarding the observation of all rules of hygiene, including personal hygiene, feeding, water supply, and billeting of troops; the systematic inspection by sanitary personnel of the territory occupied by the troops, including bath-houses, sources of water supply, slaughterhouses, bakeries, etc., and the medical inspection of the civilian population; the constant and careful sanitary reconnaissance of new areas occupied by the troops in the course of battle; prophylactic treatment of troops against possible epidemics, and the search for, registration of, and systematic treatment of chronic sufferers and carriers; extensive sanitary instructional work as a means of educating the troops and bringing about their participation in active anti-epidemic measures. On the outbreak of infectious disease the anti-epidemic measures employed include the immediate segregation of the patient for his later admission to an isolation hospital, and the disinfection of his quarters and all those who have had contact with him.

In the event of the discovery of a nidus or an outbreak of any epidemic disease it is most important that all the means of combating epidemics, including isolation hospitals, should be immediately transferred to the scene of the outbreak. In practice in the Red Army, when a nidus of infection is discovered the mobile isolation hospital and other anti-epidemic units are at once dispatched to the place where the patients are concentrated. The Medical Corps is specially equipped for the carrying out of extensive anti-epidemic measures. Depending on the general military situation and the nature of the epidemic, laundry and bath-house units, etc., are allotted to the troops in the forward positions; or in cases of necessity the existing sanitary units are strengthened by disinfection companies mobile sanitary-epidemic units from the base, etc.

The freedom of troops from epidemic diseases depends to a considerable extent on the timely sanitary reconnaissance of the territory liberated and the medical inspection of its civilian population. The Red Army Medical Corps therefore undertakes anti-epidemic work among the civilians of liberated areas as well as among the troops. The collection and analysis of data on the health of the troops and the general state of the territory occupied by them and in which they will operate and the carrying out of necessary prophylactic measures against infection and to eliminate nidi within the army area, are done under the direction of the Army Sanitary-Epidemic Unit which has special sections attached to the various army formations.

The system of anti-epidemic work among the troops is effected through the following urgent measures. First, sanitary reconnaissance is carried out uninterruptedly, and includes no only the zone in which the troops are actually quartered a the moment but also the area in which it is assumed they wil operate when they advance; secondly, a report is made at once to every branch of the medical service concerned, and first and foremost to the immediate superior, of the discovery of all foci of infection, or of anything which may affect the troops freedom from infectious diseases. The timely reporting of such occurrences makes it possible to take into consideration the slightest change in the epidemic situation, to adopt the necessary prophylactic measures, and to mobilize rapidly all means for liquidating the epidemic danger that has been discovered.

Thirdly, we have the careful planning of anti-epidemi measures based on the tasks to be accomplished by the troops the analysis of information provided by sanitary reconnaissance and the general situation with regard to epidemic diseases. The plan must include the constant and strict control of all objects of significance from the standpoint of infectious diseases; th dispatch of anti-epidemic equipment in directions where concentrations and movements of troops are in progress and also to points where there is a danger of an epidemic outbreak; th maintenance of reserve equipment to strengthen forward sanitary units and neutralize the sudden outbreak of epidemics and the working of the anti-epidemic service at definite stage of an engagement

Fourthly, the constant readiness and perfect mobility of anti-epidemic units are always borne in mind, with the rapid manœuvring of all available personnel and equipment to such changes in the military and the sanitary situation; and, fifthly we carry out the careful simultaneous mass application of al forms and methods of prophylaxis and anti-epidemic measures

The entire freedom of the Red Army from epidemic disease has been achieved by the simultaneous and correlated activit of all units concerned, and is due to the fact that anti-epidemic measures among the troops are not carried out by individua specialists but by the Medical Corps as a whole. The absenc of any serious or lengthy outbreaks of infectious diseases in the Red Army despite the extraordinarily unfavourable conditions which it meets with in its advance to the west lead us to assume with confidence that the anti-epidemic measure adopted are adequate and are fully abreast of the achievements of modern science.

In the course of the war fresh contingents of doctors and nurses have come into the Red Army, and extensive and valuable experience has been gained. The high level of medica service is ensured by the fact that the whole Red Army Med cal Corps, from general to private, is being systematically trained to improve military and medical knowledge, and is studying the new experiences which have been gained. For this purpose all medical units in institutions run planned courses of instruction; short courses for medical personnel are arranged to improve their knowledge of special branches; and numerous conferences of surgeons, physicians, epidemiologists, and workers in other specialties are held at which the experiences of the most progressive specialists and institutions are studied, summarized, and popularized.

Conclusion

The organization of the Red Army medical service does not stand still, but by the correlation of war experiences and study of the latest achievements in war medicine, its personnel and their distribution, the forms and methods of work are constantly being perfected. This is a guarantee that the Red Army Medical Corps will in the future be able to cope with the tasks with which it is faced.

TREATMENT OF GUNSHOT FRACTURES OF THE EXTREMITIES IN EVACUATION HOSPITALS OF THE U.S.S.R.

BY

Prof. NIKOLAI N. PRIOROV

In wartime the treatment of bone injuries has exceptional significance. According to data from Soviet hospitals fractures of the extremities constitute 38% of all wounds encountered during the present war. If fractures of the skull, face, spine, and ribs are added to this figure the total reaches 45 to 47%, or almost half of all wounds incurred at the front. Correct fracture treatment must involve not only restoration of lost function but restoration of fighting capacity as well and the return of an experienced and tried soldier to the Army.

Wartime gunshot fractures have these features:

1. They are open, compound, and complicated by infection.
2. Like closed fractures, they are accompanied by displacement of bone fragments.
3. They are associated with extensive destruction of soft tissue, not observed in closed fractures.
4. They are often encountered as comminuted fractures, with a large number of splinters scattered throughout the area surrounding the wound.
5. Wounded men with bone fractures are unavoidably subject to many-staged treatment in various stations and centres, beginning with field hospitals and ending in the deep rear.
6. Treatment is protracted and the results are less satisfactory than in treatment of closed fractures.

Principles of Treatment

Treatment of gunshot fractures in the U.S.S.R. is based upon the following principles: (1) First aid is administered on the battlefield at the spot where the wound is incurred, either by sanitary instructors or occasionally by other soldiers. (2) An aseptic dressing is applied to the wound and the limb is immobilized with splints made of plywood, bark, or wire netting. (3) Surgical débridement is performed at the first field medical stations.

Through-and-through wounds, with perforations of soft tissue at the sites of entry and exit, are always treated with antiseptics. The wound is always excised if there is extensive destruction of soft tissue. All devitalized and necrotic tissue is excised. Supplementary excision is performed in the presence of pockets or if an outpouring of lymph into spaces is likely. When the wounded man has not been treated for 24 hours after injury the wound is merely incised, and excision of devitalized tissue is carried out if necessary.

In treating the wound free bone splinters are removed and the periosteum is preserved; the wound is never sutured. Sulpha drugs and, more recently, penicillin are utilized. Reduction of the fracture is considered obligatory.

The following rules are observed in fracture reduction: (1) The fracture must be reduced at the earliest possible moment. (2) Reduction must be performed under general or local anaesthesia. (3) Reduction must be by manipulation or with the help of special orthopaedic tables and traction apparatus. (4) After reduction the position of the fragments must be verified by radiographs or by comparative measurements of the extremities. Plaster cast, Cramer, and Thomas splints and the Dieterich wooden splint are used for fixation of the extremities after surgical treatment. Cramer splints are preferable for injuries of the upper extremities; plaster cast or Thomas splints for injuries of the lower extremities.

Plaster casts are most often used, and are applied without cotton inner padding. Practice has shown not only that they effectively immobilize the fracture but that they are very effective in draining wound seepage. They keep the wound undisturbed and prevent secondary infection. The patient wearing a plaster cast must receive careful attention. High temperature, complaints of illness, pains in the extremities, all stress the necessity for examination and observation of the wound either by means of cutting a window in the cast or, occasionally, by removing the cast completely. Closed plaster casts must not be used if the presence of gas infection is suspected or if there is a possibility of haemorrhage.

Blood transfusion is widely used in treating shock and loss of blood. All wounded men receive antitetanus serum, and anti-gas-gangrene serum is also given in the presence of extensive and severe injuries to the tissue. The wounded, if transportable, are evacuated to rear hospitals by ambulance, hospital train, and aeroplane.

A network of special hospitals has been established for treatment of gunshot bone fractures. Distribution of the wounded among these hospitals is based upon the severity and location of their wounds. For those with slight injuries of the fingers, wrist, forearm, and foot there is a special hospital where they can simultaneously receive surgical treatment, physiotherapy, gymnastics, and occupational therapy. A separate hospital also exists for patients with injuries of the thigh, lower leg, and upper arm. This system makes possible correct allocation of requisite apparatus to the various hospitals, and also facilitates the assignment of cadres of specialists. It enables doctors and nurses working with a uniform contingent of wounded men to master more speedily the correct methods and technique of treatment.

Treatment in Base Hospitals

Patients arriving in base hospitals are subject to careful observation, which includes *x* rays, laboratory analysis of blood and urine, and bacteriological examination if necessary. If phlegmon or inflammatory processes exist in the region of the injury, especially when primary débridement has for some reason been omitted, secondary excision of the wound is performed. A wide incision is made and foreign matter, free bone splinters, and necrotic tissue are removed. Reduction is carried out simultaneously if the condition of the patient permits, the fragments being brought into juxtaposition and occasionally even fixed by suturing. Such delayed reductions are performed as late as four and even five months after injury if there is extensive displacement of bone fragments and union has not been secured. The wound is not sutured after secondary surgical débridement and late reduction; it is tamponed and commonly treated with antiseptics (including sulpha drugs and penicillin). Our observations enable us to recommend delayed reduction to surgeons with sufficient experience. In most cases extremely good results have been noted after these operations. A flare-up of infection occurs as a rare complication in individual cases.

Two methods are used for the treatment of gunshot wounds in rear hospitals: (1) the plaster cast and (2) skeletal traction. The plaster cast is employed in treating fractures of the upper arm, forearm, foot, and lower leg, and in all cases in which complications occur during the course of illness. In most instances closed plaster casts, in which openings have been made as a precautionary measure, are employed. Skeletal traction is used in fractures of bones of the thigh, lower leg, and upper arm, in the presence of displacement, and when complications are absent or have already been overcome, as well as in closed fractures. Thus, plaster cast and skeletal traction are not mutually exclusive but, on the contrary, supplement each other. In certain cases treatment begins with the closed plaster cast and concludes with skeletal traction; in others it begins with skeletal traction and concludes with the closed plaster cast.

In gunshot wounds union is protracted. To stimulate this process we make wide use of physical therapy, quartz, paraffin, and ozocerite, as well as the antireticular cytotoxic serum of Prof. Bogomoletz and the tissue therapy of Prof. Filatov.

Considerable importance is attached to good nutrition and the prescription of vitamins. At the earliest moment that the patient's health permits, general and specialized physiotherapy (gymnastics) are used in order to improve his general condition and prevent muscle debility, contractures, and limitation of joint mobility.

Complications

A variety of complications may occur in the treatment of bone injuries. These include: (1) abscess, phlegmon, pus pockets; (2) osteomyelitis; (3) haemorrhage; (4) delayed consolidation, non-union, and pseudarthrosis; (5) malunion; (6) contractures, limitation of mobility, and ankylosis of joints; (7) sepsis. Each of these complications demands timely discovery, diagnosis, and special treatment.

Conclusion

We consider that considerable success has been achieved in our treatment of gunshot fractures. More than 50% of our wounded with bone injuries are returned to the Army. Complications in wounds of the thigh and lower leg have sharply decreased and the number of amputations considerably diminished.

AMPUTATION OF THE EXTREMITIES, AND PROSTHESIS, IN THE U.S.S.R.

BY

Prof. NIKOLAI N. PRIOROV

In gunshot wounds, amputation of the extremities is in many cases the sole means of saving life. In comparison with previous wars the number of amputations in the present war, both in the rear and at the front, has diminished by half. The reasons for this decrease are as follows: (1) approximation of surgical aid to the wounded; (2) application of first aid soon after injury; (3) radical excision of the wound in medical sanitary stations near the front and in field hospitals; (4) the use of antitetanus serum in all cases of trauma and of anti-gas-gangrene serum in cases of severe trauma; (5) wide use of sulphonamide preparations; (6) employment of blood transfusion, without exception, where indicated; (7) the possibility of retaining patients with severe wounds of the extremities in front-line hospitals until their condition becomes less grave; (8) complete immobilization of the injured parts.

We consider the plaster cast the best method of immobilization. The majority of amputations are performed at the front, and only an insignificant number—approximately one-fifth of all amputations—are carried out at hospitals in the rear.

Reasons for Amputation

The first and chief reason for amputation (up to 40%) is severe destruction and crushing of soft tissue, bones, and joints, with acute disturbance to nutriment of the extremities. The second reason is the tearing away of an extremity by shell fragments, bombs, etc., the remaining part being connected to the body by a mere patch of skin, thus necessitating only completion of amputation. Third, the presence of sudden and rapidly developing gas infection when other methods of controlling it are unsuccessful. Fourth, gangrene of the extremities, after injury to the blood vessels, burn, freezing, etc.: amputations of this type are not numerous (from 1 to 2% of the total). Fifth, the septic condition of the patient after trauma of the extremities, in the presence of phlegmon and purulent pockets, and in acute osteomyelitis, when all methods of treatment prove unsuccessful and it becomes necessary to sacrifice the injured part. Amputations as a result of these conditions constitute, according to our data, 7 to 9% of the total. They are performed in hospitals close to the rear.

Methods of Amputation

We use both chop and guillotine methods, but greatly prefer the latter because enough skin is saved to allow of a later skin graft. In individual cases we cut out one or two skin flaps, which, if conditions are favourable, can later be used to close the amputation wound. In order to protect the flap from infection it is rolled into tube form and sutured. Primary amputations are never sutured.

We consider the following safeguards obligatory in amputation: (1) To prevent the patient from becoming chilled during the operation and to provide him with heat (warm blankets, heat pads, etc.). (2) To give blood transfusions before and after operation. In primary amputation blood is transfused in large quantities; in secondary amputation it is transfused in small quantities. (3) To apply a tourniquet during the operation and not to lose a single drop of blood. (4) To operate under anaesthesia. We commonly use inhalation, intravenous, and local anaesthesia, and also freezing. (5) Observation and care, in the field hospitals where the amputation is performed, for a period of two or three days after operation.

Treatment of Stump

The reason for amputation, and the methods of amputation just indicated, determine subsequent treatment of the stump. An infected stump is never sutured. When it progresses favourably we recommend an initial dressing on the eighth or tenth day, preferably under anaesthesia. In such cases the amputation site is usually clean and covered with fresh granulation tissue, and inflammation is absent. Secondary suture, preferably with the use of plastic buttons, is possible, the edges of the wound being gradually approximated by tightening the suture. These measures guarantee a good stump for prosthesis and preclude the necessity for re-amputation.

When the stump does not progress favourably, owing to the presence of infection—phlegmon, osteomyelitis, phlebitis, etc.—the wound is treated by the usual surgical measures: supplementary excision, antiseptics (sulphonamide preparations, penicillin, gramicidin, bacteriophage, and others), and also by physiotherapeutic methods. The stump wound is treated with the aid of a Thomas brace in order to prevent the development of contractures.

A significant number (up to 80%) of amputation stumps are diseased or defective. Diseases of the stump comprise non-healing wounds, ulcers, osteomyelitis, ligature fistula, exostosis, neuritis, pains in the stump, phlebitis, disorders of the skin, and contracture. Defects of the stump consist of excessively long or short stumps, disarticulated stumps of the knee-joint, ankle-joint, wrist, and shoulder, stump scars with bone adhesions, conical stumps, ankylosis, and defects following osteoplastic operations.[1]

In treating diseases of the stump and to remove defects, physiotherapy, heat, mud, tar, paraffin, and ozocerite are extensively used. Cases that do not respond to conservative treatment are dealt with as follows: (*a*) by skin grafting; (*b*) by grafting adjacent tissue; (*c*) by excision of scar tissue, with skin grafting; (*d*) by removal of adhesions and ligatures; (*e*) by removal of neuromas and neurolysis; (*f*) by sequestrectomy; (*g*) by re-amputation.

Re-amputations form from 40 to 60% of all operations on the amputation stump and need special attention. The three chief points arising with regard to re-amputation are: (1) indications for re-amputation; (2) time of re-amputation; (3) method of re-amputation. According to data compiled during the war by Soviet hospitals, indications for re-amputation have occurred in the following proportions: non-healing wounds, up to 60%; osteomyelitis, from 17 to 20%; extensive scars with bone adhesions, 10%; exostosis, pains, etc., 10%.

The time for re-amputation can never be a matter of indifference. From a wide experience we have reached the conclusion that the ideal time is the third month after primary amputation, when good granulation tissue exists, inflammation and oedema have disappeared, and dense scars are not present. In cases of gas infection re-amputation is delayed until the six to tenth month.

The bone, in re-amputation, is dealt with by the Bunge method. The bone canal is tamponed with a section of muscle, bleeding vessels are carefully tied, the nerve is cut at a fairly high level with a razor blade, and drainage tubes are inserted for one day. The use of the osteoplastic operations of Pirogov, Bier, Gritti-Stokes, and Kirschner is widely recommended.

Preparation of Stump for Prosthesis

From the very beginning of treatment very careful attention is given to the preparation of the stump for prosthesis. In the first stage of stump treatment binding scars, contractures, and limitation of motion must be prevented. In the second stage, after the wound has healed, physiotherapeutic methods of treatment are used ; these include massage of the extremities—omitting the stump itself—contrast baths, and electric stimulation. Stump exercises and gymnastics for the amputee, stump-wrapping, and training to accustom the stump to withstand pressure are started early, and therapeutic prostheses are extensively used. Stump preparation continues for two to three months.

Organization of Prosthesis Supply

In the Soviet Union a network of special hospitals have been established for the purpose of supplying prostheses. Each hospital includes a department of orthopaedics where the stump is treated, a department of physiotherapy where it is prepared for prosthesis, and a prosthesis department where the artificial limbs are completed and fitted. Our prostheses are made of wood, leather, or emolyten, and in the main our system of supply is divided into two sections—the manufacture of parts and the assembly of the finished limb. Several factories exist for the manufacture of unassembled metal and wooden limbs. Assembly of the prostheses is done by regional workshops distributed throughout the Soviet Union.

Special attention is given to supplying prostheses for wounded men with bilateral arm amputations. Either a Krukenberg operation or phalangization is performed, and the amputee is provided with an active artificial hand.

A healed amputation stump and a suitable prosthesis are essential for re-establishing the patient's working capacity and providing him with employment. Up to 90% of our amputees, after being treated and supplied with artificial limbs, return to the factories, plants, and other establishments where they were employed prior to the war. Only work can complete their rehabilitation ; only work can heal their severe psychic wounds and restore their shaken nerves.

OSTEOPLASTIC RE-AMPUTATION OF THE THIGH

BY

Dr. ALEXANDER KOTOV

Many surgeons in the U.S.S.R. and in other countries consider end-weight-bearing stumps preferable to other types from the prosthetic point of view. These permit an artificial limb to be lighter in weight and simple in construction, and in addition they guarantee stability in walking, due to the fact that the amputee in a way "feels the earth under his feet." Non-end-weight-bearing stumps in many cases involve permanent pressure on the tuber ischiadicum, which is difficult to support and which hampers walking.

The objections raised by critics of end-weight-bearing stumps lie not in their disagreement with what has just been stated but basically in that in course of time the supporting capacity of the stump lessens and even completely disappears. It seems to us, however, that this does not justify depriving the amputee of the possibility of using an end-weight-bearing stump, even if only for a limited period.

End-weight-bearing Stumps

We consider that below-knee amputations provide the best means of obtaining end-weight-bearing stumps by operative procedure. According to our observations in the Soviet Union, the Pirogov, Syme, Bier, and Kirschner operations all give excellent results. Because of this they are widely used in our hospitals in cases requiring below-knee re-amputations. It was possible, by use of the methods mentioned, to provide the majority of patients with prostheses that reached no higher than the level of the knee-joint.

In re-amputation of the thigh there is less possibility of securing end-weight-bearing stumps. The Gritti-Stokes osteoplastic amputation, in the opinion of various authorities and according to our own observations, gives a good end-weight-bearing stump in the region of the lower third of the thigh. Some writers claim that they get a stable end-weight-bearing stump in the middle third of the thigh by that method. Conditions of war, however, especially in amputation centres, limit the use of this operation, both for thigh and for below-knee amputations. It is first of all excluded when thigh stumps do not include the patella ; and, secondly, its use is seldom indicated on stumps of the upper third of the lower leg. Thus, in thigh re-amputations we do not regard the osteoplastic operation as an accepted method of securing an end-weight-bearing stump.

On the basis of data gathered from all hospitals under the control of the People's Commissariat of Health of the U.S.S.R., the number of thigh amputations following war trauma is approximately equal to the number of below-knee amputations. They constitute, however, a far more difficult group with respect to restoration of lost function.

Owing to the absence of two groups of major joints a thigh case finds walking much more difficult than a case with amputation of the lower leg. In addition, the surface that can be utilized to fasten the socket of the prosthesis is only one-half or one-third of that available in below-knee amputations. Finally, in non-end-weight-bearing stumps of the thigh the only anatomical point of pressure in walking with the prosthesis is the tuber ischiadicum. We are in agreement with those who, having observed the prostheses of patients with thigh amputations, point out that their adjustment to weight-bearing on the tuber ischii is often a lengthy and unpleasant procedure.

These factors forced us to seek a means of alleviating the condition of this group long before the outbreak of the present war. At the clinic of the Ukrainian Institute of Orthopaedics and Traumatology in Kharkov physiotherapeutic methods of accustoming the thigh to pressure after re-amputation were employed. Our observations showed that to secure an end-weight-bearing thigh stump by means of this method long and unwearying persistence was required, but the results completely justified the effort.

As a result of his training the patient with an end-weight-bearing thigh stump showed incomparably greater stability and ease in walking than when he had a non-weight-bearing stump. In addition the majority of amputees, after therapeutic treatment, began to walk with a mobile artificial knee-joint and refused to wear a lock, which they had previously insisted upon in order to prevent mobility. In some cases the end-weight-bearing stump enabled patients to abandon completely the use of the ischium for support.

During the war, which has made wide use of operative procedures for treatment of the stump possible, the idea arose of employing the osteoplastic method to increase the ability of the thigh stump to bear pressure. Our use of the Kirschner method for re-amputations of the lower leg in the amputee hospital at Seipolatinsk, Khazakstan, gave good results, and we decided to utilize the principle of this operation to obtain a pressure-bearing thigh stump. During ten months of work we performed 15 osteoplastic re-amputations of the thigh stump in the middle third. The post-operative wound healed very quickly in all these cases. We began educating the stump to weight-bearing on the twelfth to the fourteenth day after operation, exercising it a few times daily. At the beginning of the second month after operation the amputee was supplied with special crutches fitted with a platform for supporting the stump. The walking time was increased daily. Later this group of amputees were supplied with end-weight-bearing prostheses having free mobility of the knee-joint.

Technique

The technique we use in osteoplastic re-amputation is very simple. A flap of skin sufficient to cover the lower surface of the stump is cut out on the anterior aspect of the thigh. The skin on the posterior surface is divided almost perpendicularly to the bone of the extremity. After this the muscle layers are divided conoidally and the bones of the thigh are sawn through. We saw off a ring-shaped bone transplant, 0.5 to 0.75 cm. thick, from the proximal end of the amputated bone and divide it into several sections. After appropriate modification the transplant is introduced into the bone-marrow canal, closing it. The muscles are then stitched in layers and the skin sutured. In some cases the diameter of the bone transplant enables us to fit it into the bone-marrow canal without division into sections, thus facilitating the operative technique.

Our observations relate to only a small number of cases and are too recent for definite conclusions to be drawn. Nevertheless the results have been so satisfactory that we feel justified in giving them wider publicity.

TRAUMATIC URAEMIA

BY

CLIFFORD G. PARSONS, M.D., M.R.C.P.

(From an E.M.S. Base Hospital)

Just as the original draft of this paper was completed there appeared an article by Darmady and his colleagues (1944), writing from the R.A.F. casualty clearing station which feeds this E.M.S. base hospital. They described 8 patients who developed uraemia a few days after being wounded by high-explosive missiles. Oliguria and vomiting were constant features in these cases, and six of the patients died. Reference was made to similar cases described during both the present and the last war, but no mention was made of a paper on the subject by Duval and Grigaut (1918).

In the hope that further light may be shed on the mechanism responsible for the azotaemia two further cases are here reported. Both these patients were healthy young soldiers whose wounds caused such extensive muscle and vascular damage as to necessitate amputation; shock was severe and was treated by transfusion of blood and plasma; infection was well controlled by early surgery and the administration of penicillin and sulphanilamide. Uraemia developed rapidly and was undoubtedly responsible for the death of one of the patients, whose wounds were not sufficient in themselves to cause a fatal outcome. Looking back through our case records, it seems probable that other unrecognized examples of the condition may have passed through our hands.

Case I

Soldier aged 19. Penetrating wounds of both knees and left arm on Aug. 15, 1944; right popliteal artery severed. No note of tourniquet. Wound toilet and amputation through right knee 17½ hours after injury; B.P. 130/65, "not shocked"; A.T.S. 3,000 units; A.G.G.S. 10 c.cm. intravenously; 2 pints blood and 5 pints plasma. 660,000 units penicillin intramuscularly by Aug. 22; sulphanilamide 2.5 g., and sulphathiazole administered in unknown quantity.

Blood Counts of Case I

Date	R.B.C. (mill.)	Hb % (Sahli)	W.B.C.	Differential Count (%)

Aug. 18.—Mental condition disturbed; R.B.C. 2,450,000, Hb 54%. Severe mental confusion continued; psychiatric examination advised.

Aug. 25.—Admitted to this hospital (Mr. A. B. Watson). Still in similar state; completely disorientated, uncooperative and unable to understand questions; general condition poor; large sacral bed-sore. Wounds dressed under anaesthesia—clean. Unable to pass urine before going to theatre; 30 oz. of *normal* urine withdrawn by catheter. Hb 45% (record of blood counts in accompanying Table); 2½ pints blood given. Particulars of fluid balance summarized in Chart; the figures for the first 5 days are inaccurate, as he was incontinent, some specimens being lost.

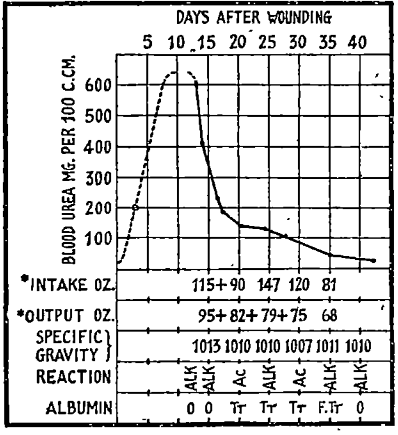

Chart showing details of fluid balance in Case 1.

* Average of previous five-days period.

Aug. 28.—Taking fluids well. Still drowsy, irrational, and incontinent. Respirations deep and slow; dry skin, fishy odour, and uraemic tongue. No oedema. Urine: Sp. G. 1013, alkaline, no albumin, no sugar, sulphanilamide crystals present. Blood urea over 600 mg. per 100 c.cm. (value approximate only at this level; subsequent determinations on Chart). It was discovered at this point that since admission the bed-sore had been dusted daily with sulphanilamide, and that sodium citrate 30 gr. t.d.s. had been given without instruction; both discontinued.

Aug. 31.—Rational and continent. B.P. 140/70. A few small haemorrhages and one white plaque seen in retinae; arteries of fundi a little prominent.

Sept. 1.—Urine: albumin and a few red cells; urea concentration normal. Running slight pyrexia due to low-grade infection of left knee-joint; amputation stump healthy.

Sept. 5.—Further course of penicillin started (650,000 units). Agranulocytosis noted; van den Bergh negative. Pentnucleotide 10 c.cm. 3-hourly and blood 4 pints, followed by rapid improvement in blood picture. The leucopenia was undoubtedly due to sulphanilamide absorbed from the bed-sore, for the blood sulphanilamide on Sept. 9 was 4 mg. per 100 c.cm.

Sept. 20.—Ocular fundi normal; B.P. 140/90; slight oedema of left leg, which subsided within 2 weeks.

Oct. 4.—Van Slyke's urea-clearance test, 94 and 108% of normal function; urea concentration normal.

Oct. 10.—Re-amputation of right femur and removal of foreign bodies from left knee. Considerably shocked; 2 pints blood given. Blood urea after transfusion, 27 mg. per 100 c.cm. Recovery rapid. Nocturia persisted until mid-October, but urine normal from Sept. 27. Subsequent course of illness uneventful.

Nov. 11.—Simple water dilution test revealed inadequate dilution and imperfect elimination of fluid. (50 oz. fluid given at 8 a.m. Total fluid passed between 9 a.m. and noon, 24 oz.; lowest Sp. G., 1010. Normal should exceed 50 oz., with dilution to 1002 or less.)

Nov. 13 and Dec. 5.—Simple water concentration tests showed defect. (Fluids restricted to 1 pint for 24 hours. Total output in the two tests, 12 oz. and 21½ oz.; highest Sp. G., 1024 and 1025. Normal less than 30 oz. and more than 1027.)

Nov. 15.—Excretion pyelography normal.

Case II

Soldier aged 25. On Nov. 4, 1944, sustained dirty wound of right arm, with extensive muscle damage, disorganization of elbow, and division of ulnar vessels and ulnar and median nerves. Tourniquet applied until arm was amputated at fracture site 5 hours later. Pulse 92; blood pressure unobtainable before operation. A.T.S. and

A.G.G.S. presumably given; 5 pints blood and 3 pints plasma. Penicillin administered locally and intramuscularly; total dose recorded 350,000 units, but was probably more. No record of sulphanilamide.

Nov. 8.—Stump satisfactory when dressed under anaesthetic; was unable to pass urine before operation.

Nov. 10.—Admitted to this hospital (Mr. Lionel E. Jones). General condition good; sutured amputation stump clean. Occasional hiccups. Intake 6 oz. Urine 14 oz., vomit 4 oz.

Nov. 11.—Still has hiccups; tongue dry; blood urea 500 mg. per 100 c.cm. R.B.C. 2,680,000, Hb 46%. Intake 77 oz. Urine 33 oz., vomit 28 oz.

Nov. 12.—Hiccups occurring with every inspiration; uraemic tongue; drowsy. Occasional twitching of left arm; C.N.S. normal, fundi normal. B.P. 170/70. Liver slightly enlarged. Stump clean; slight oedema of right shoulder. Considerable bruising and swelling left elbow region, probably due to leak from pentothal. Oedema of sacral region; no venous engorgement. Magnesium sulphate enema and morphine. Urine: neutral, Sp. G. 1012, albumin +, occasional R.B.C., no casts or crystals, spectroscopic examination normal, urea 1.8 g. per 100 c.cm., NaCl 0.12 g. per 100 c.cm., benzidine reaction negative. Intake 51 oz. by mouth, 20 oz. intravenous 5% glucose. Urine 70+ oz., vomit 3 oz. In evening developed pulmonary oedema. Retention of urine at 9.30 p.m.; catheterized. Died 11.15 p.m.

Necropsy 16 Hours After Death.—Amputation wound healthy; microscopical examination of muscle showed necrosis with recent haemorrhages and infiltration with polymorphs and lymphocytes, but no evidence of gas gangrene. Trachea contained frothy fluid; heavy waterlogging of lungs confirmed by microscopy; 1 pint clear fluid in right pleural cavity. Heart normal. Liver large and pale; the cells were separated by wide sinusoids and contained a few small fatty globules; some of the portal tracts contained phagocytic cells laden with brown pigment. Spleen, pancreas, suprarenals, and gut normal. Kidneys 8 and 8¾ oz., slightly oedematous, glistening and with well-defined markings; little fatty change seen microscopically; glomerular tuft congested but not grossly abnormal; some tubules were dilated and contained hyaline and granular casts staining orange with eosin, desquamated cells, wisps of hyaline material, occasional polymorphs, and phagocytic cells with ingested orange pigment. In addition a few crystals were seen in some of the tubules; they were grey in colour and spherical with radial striation; some were broken up into a mass of smaller crystals each resembling a small scalpel blade. Staining for free iron negative. In the interstitial tissue of the kidneys there were a few collections of lymphocytes, plasma cells, and eosinophils. Vessels normal. (Microscopical examination by Dr. J. L. Edwards.)

Discussion

It is obvious that in these patients the production of urea is more rapid than its elimination. In the great majority of recorded cases there has been severe damage to one or more limbs, often involving large vessels. Haemorrhage and shock have therefore been the rule and transfusion has invariably been necessary. Darmady and his colleagues (1944) have remarked that the condition is in some ways like the crush syndrome, and it should also be noted that it bears a resemblance to the azotaemia of haematemesis.

It was shown by Taylor and Lewis in 1915, and confirmed by many others since that time, that when bleeding reduces an animal's blood volume to about 50% of normal the blood urea rises. This increase may be considerably accentuated by repeated haemorrhage and by associated dehydration (Meyler, 1935). Wallace and Sharpey-Schafer (1941) were unable to demonstrate a significant rise of blood urea in blood donors unless there was a pre-existing renal defect.

Black (1942), in a full account of azotaemia in gastroduodenal haemorrhage, points out that the condition is due to a functional renal impairment associated with accelerated breakdown of tissue protein, as well, of course, as absorption of nitrogenous material from the blood in the bowel. He goes on to say: "For the most part extrarenal azotaemia from whatever cause can be traced back to a reduced blood volume or disturbed water and salt metabolism, or both. Either of these primary causes can produce both increased protein katabolism and functional renal failure, and it is probable that both these secondary changes must be present before azotaemia develops." In traumatic uraemia, at any rate during the period immediately after wounding, the dietetic protein, 80 g. of which will raise the blood urea by about 50 mg. per 100 c.cm., can play little or no part as a source of urea; it must therefore be derived from tissue breakdown. The rapid rise of blood urea is consequently suggestive of an accelerated protein katabolism, especially when considered in conjunction with the speed at which weight is lost by these patients. There is no doubt that they all suffer from dehydration and oxygen deprivation due to anaemia, vasoconstriction, and reduced blood volume—factors quoted by Black as increasing tissue-protein katabolism. It is therefore probable that the manufacture of urea from tissue proteins is abnormally rapid after severe traumatic haemorrhage.

It is remarkable that the livers of these patients carry out their task so efficiently, since often there is evidence of hepatic damage. Some of the patients are jaundiced and changes in the liver cells are usually demonstrable at necropsy. The azotaemia of acute necrosis of the liver chiefly concerns the non-protein nitrogen other than urea, and if the blood urea is high, as sometimes happens in cases of carbon tetrachloride poisoning, renal failure rather than liver damage is responsible (Forbes, 1944). Incidentally Forbes mentions a case in which recovery of kidney function was complete 46 days after the urea clearance had been reduced to less than 10%.

As a normal kidney can rapidly clear large amounts of urea from the blood stream, there can be no doubt that impairment of renal function is the major factor in the production of traumatic uraemia. Darmady and his colleagues state that oliguria is always present, and this is certainly to be expected during the phase of haemorrhagic shock, for it has been shown that this state causes an active constriction of the renal arteries with consequent reduction in urinary excretion (Lauson *et al.*, 1944). Unfortunately no information is available about the urinary output of either of our patients during the immediate post-traumatic period, but the second patient was passing only small quantities when he first came under our observation. It is improbable that complete anuria persisted for more than a few hours at most, for such an event could scarcely pass unnoticed in a general hospital. The state of shock which might have led to cessation of urinary excretion was rapidly corrected by transfusion, but it has been shown that diminution of renal blood flow may persist after haemorrhagic shock even when the systemic blood pressure has been restored to normal by emergency measures (Lauson *et al.*, 1944). There is no evidence that the transfused blood was incompatible. The other possible causes of renal impairment tend to produce their effects after a few days' delay and do not satisfactorily explain the onset of symptoms so shortly after wounding. Sulphonamides, for example, when given in therapeutic doses are unlikely to damage the kidney sufficiently to suppress formation of urine until almost a week has passed. Likewise, after a crushing injury anuria is commonly delayed for several days, although it has been shown that injections of myotoxin will cause instantaneous anuria in rats followed, in non-fatal cases, by oliguria and eventually by diuresis (Bielschowsky and Green, 1943).

The diuresis present in the first patient was a stumbling-block to diagnosis. When a man is passing daily over 100 oz. of urine, in which no albumin or abnormal cellular elements can be found, it is unnatural to suspect that his blood urea is over 600 mg. per 100 c.cm. It will be observed that the second patient also developed a diuresis in the later stages and that the urea concentration was good; but despite this he retained fluid in the subcutaneous tissues and pleural cavity, and eventually died of pulmonary oedema. The diuresis was no doubt stimulated as much by the high blood urea as by the high fluid intake; a similar phenomenon has often been observed during recovery from the azotaemia of haematemesis, and during this stage there is no apparent abnormality of renal function. Darmady and his colleagues (1944) found that the defective urea clearance occurring during the early phases of traumatic uraemia became normal as the patient improved.

The renal function of our surviving patient was normal when examined by the generally accepted tests, and there was certainly nothing to suggest pre-existing kidney damage. Although the concentration of urea in the urine was usually low, no doubt because of the diuresis, Fowweather's concentration test was normal. Urea clearance (van Slyke) and elimination of uroselectan were also normal. It is therefore interesting and important that simple water dilution and concentration tests proved more sensitive in demonstrating a renal defect which has persisted. When a large amount of fluid was drunk it was excreted too slowly and the specific gravity of the urine failed to fall as low as it should have done, indicating abnormal glomerular filtration. Neither did water deprivation raise the specific gravity to the levels which ought to have been reached —an indication of impaired tubular absorption.

The transient albuminuria in this case was almost certainly due to sulphanilamide poisoning: it coincided with the discovery of crystals and red cells in the urine and heralded the appearance of agranulocytosis. (Incidentally this emphasizes once again the danger of uncontrolled application of sulphanilamide powder to ulcers; the response of the severe leucopenia to massive doses of pentnucleotide is also worthy of notice.) If the albuminuria had been due to the effects of the original injury, as was presumably the case in the second patient, it should have been evident when the blood urea was at its maximum. During the post-traumatic period neither patient passed red cells in excess no casts were found, and spectroscopic examination for haemoglobin and muscle pigments was negative.

The kidneys of the second patient were examined post mortem and were similar to those already described (Darmady *et al.*, 1944), the pathological lesions being comparable to those of the crush syndrome and largely confined to the tubules. In addition a few sulphanilamide crystals were present. The changes were certainly insufficient to explain urea retention on the purely mechanical basis of tubular obstruction, and the glomeruli were comparatively healthy. The blood urea does not rise in nephrosis in which pathological changes are confined to the tubules. It therefore seems more likely that the cause of renal failure and of the damage to the tubules is anoxia resulting from vasoconstriction of the renal arteries during the stage of shock, aggravated by blood loss, a fall in blood pressure, and dehydration. This supposition is favoured by the demonstration of similar alterations in the tubules after temporary clamping of the renal vessels (McEnery *et al.*, 1927) and by the theory propounded by Maegraith and Findlay (1944) that peripheral vascular atony with redistribution of renal blood flow explains the suppression of urine in blackwater fever. The action of myotoxin may be accounted for in a similar manner. Oedema of the kidneys and rupture of some of the renal capillaries occur during the anoxic period, and may be responsible for the slow recovery of renal function after the systemic blood pressure has risen to normal.

It has not yet been decided how these cases should be treated. Arguing on purely theoretical grounds, which may be fallacious, the best hope of improvement should lie in the early restoration of an adequate blood flow to the kidneys. Caffeine is said to dilate the renal vessels, and although its effectiveness in these cases is doubtful it can certainly be administered in full doses without harm. Giving oxygen in high concentrations might also be of value, but there has been considerable disagreement about its success in the treatment of shock (*vide* annotation in the *British Medical Journal*, 1942). It would seem particularly important to raise the pressure, volume, and oxygen-carrying capacity of the blood to normal levels, and this can only be achieved by the continuous administration of carefully matched blood, and then with difficulty. Black and Smith (1941) have demonstrated that blood is much more effective than plasma in promoting the excretion of urea when azotaemia develops after haematemesis. Fluids should certainly be provided in abundance, but because these patients tend to develop subcutaneous and pulmonary oedema it should be given by mouth or by rectum and not intravenously.

Summary

Two further cases of traumatic uraemia are reported. It appears that the condition may be relatively common in modern warfare, especially when severe damage to a limb involves large blood vessels. Evidence is given that urea manufacture from tissue protein is increased in the early stages of the illness, and reasons are advanced in support of the view that urea retention is due to renal anoxia. It is suggested that blood transfusion should be the most important factor in treatment. During the recovery phase diuresis is pronounced and the usual renal function tests may show no abnormality. Simpler tests have revealed kidney impairment in one of the cases described.

One patient had severe leucopenia as a result of sulphanilamide poisoning, and responded rapidly to injections of pentnucleotide.

I am indebted to my surgical colleagues for permission to quote their cases, and to Dr. J. L. Edwards for the histological report.

THE CEPHALIN-CHOLESTEROL FLOCCULATION REACTION AS A TEST OF HEPATIC FUNCTION

BY

ARCHIBALD DICK, M.D., B.Sc.
Assistant Pathologist, Royal Northern Infirmary, Inverness;
Formerly Hall Fellow in Medicine, University of Glasgow

(From the Gardiner Institute of Medicine, University of Glasgow, and the Western Infirmary, Glasgow)

The cephalin-cholesterol flocculation reaction was first introduced by Hanger (1939) as a test of hepatic efficiency. It is recognized that many of the liver function tests in common use fail to detect early or mild liver damage; positive results are often found only in the advanced stages of the disease when clinical symptoms are already manifest. The cephalin-cholesterol flocculation test has been shown by several American workers (Hanger, 1939; Pohle and Stewart, 1941; Rosenberg, 1941; Nadler and Butler, 1942; Mateer *et al.*, 1942; Yardumian and Weisband, 1943) to be an extremely sensitive test in the early detection of hepatic insufficiency. The test was found to be of considerable value in prognosis in cases of acute infective hepatitis; the persistence of a strongly positive reaction indicates severe liver damage. A further important claim was its value in the differentiation of jaundice due to parenchymatous disease of the liver from that due to obstruction of the biliary passages. It therefore promises more diagnostic help than certain of the earlier tests, in which similar results are obtained in all types of liver disease.

The value of the cephalin-cholesterol flocculation test of hepatic function has not yet been conclusively established in this country. It falls into the category of empirical procedures rather than a definite test of any known hepatic function. The exact mechanism of the test is poorly understood (Hanger, 1939). It is relatively inexpensive to carry out; few reagents are required, and it is more easily performed than other tests in common use. The object of this paper is to present results of this test in hepatic and biliary disease; no attempt is made to explain the mechanism of the reaction.

Method

The method employed was that described by Hanger (1939). First, enough cephalin was obtained by extraction from sheep's brain to last for about one year. Sheep's brains (two or three) were dehydrated by three extractions with acetone, and the dry powdered tissue was three times extracted with ether. The ether extracts were concentrated and the crude cephalin was precipitated by the addition of four volumes of absolute alcohol. The resulting precipitate was dissolved in the minimum amount of ether; the accompanying cerebroside impurities were precipitated by chilling to 5° C. and removed by centrifugation. The supernatant ether solution was again precipitated with four volumes of absolute alcohol, chilled, and the precipitate filtered, washed with alcohol and acetone, and desiccated. The cephalin preparation is a brown powdery material. Hanger (1939) suggested that freshly prepared cephalin was too sensitive and that it should be ripened for some months before use.

A stock solution was then prepared by adding 300 mg. of cholesterol and 100 mg. of cephalin to 8 c.cm. of ether. This stock solution, well stoppered, was kept in a refrigerator at 0 to 5° C. In order to prepare the emulsion 35 c.cm. of distilled water was heated to 65–70° C., and 1 c.cm. of the stock solution was slowly added, with frequent stirring. The emulsion was heated to boiling-point and allowed to simmer until the volume was reduced to 30 c.cm. This was cooled to room temperature, and 1 c.cm. of the emulsion was added to a centrifuge tube containing 0.2 c.cm. of the patient's serum and 4 c.cm. of freshly prepared 0.85% sodium chloride. The centrifuge tube was stoppered, shaken, and left at room temperature. After 24 hours note was made of the presence of flocculation, which was designated "zero" to "4-plus." The serum should be used immediately or else kept in an ice-box for not longer than 6 hours. The final reading should be made in 24 hours, as normal sera may cause positive flocculation in 48 hours (Clay and Moore, 1942).

Previous workers (Pohle and Stewart, 1941; Clay and Moore, 1942) showed that the test was positive in a small percentage of normal individuals and in those suffering from various systemic disorders. It therefore appeared necessary, in assessing the value of this test, to examine the sera of such individuals as well as the sera of those with definite hepatic disease. Accordingly the test was applied to the sera of three different groups: (1) Healthy individuals attending as blood donors. (2) Patients suffering from a variety of systemic diseases without clinical evidence of hepatic disease. (3) Patients suffering from hepatic or biliary disease.

Results

(1) Sera of Normal Individuals

The test was applied to 100 individuals attending as blood donors who were regarded as healthy. Only one of the 100 sera examined gave a positive reaction (4-plus) after 24 hours. This patient had a history strongly suggestive of a mild attack of infective hepatitis a few weeks previously; the serum gave an indirect van den Bergh reaction of 0.9 mg. per 100 c.cm. This case can therefore be excluded from the controls because there was evidence of hepatic disease; in 99 normal persons the test was negative.

(2) Sera of Those Suffering from a Variety of Systemic Disorders

This group includes 164 patients; 123 were in the wards, and 41 attended as out-patients on account of rheumatoid arthritis. The results are shown in Table I.

Table I.—*The Cephalin-Cholesterol Flocculation Test in Various Non-hepatic Diseases*

System Involved	No. of Cases	No. with Flocculation
Cardiovascular	14	0
Haemopoietic	17	4
Respiratory	17	4
Alimentary	29	2
Renal	8	1
Nervous	8	0
Endocrine	13	0
Bones and joints	58	2
Total	164	13

Table I shows clearly that flocculation may occur in those suffering from conditions not primarily hepatic. Positive reactions were encountered in 13 patients (7.7%), and details of these are shown in Table II.

Table II.—*The Disease and Degree of Flocculation in Cases with a Positive Reaction*

Case	Disease	Degree of Flocculation
1	Pernicious anaemia	++
2	Iron-deficiency anaemia	++++
3	Malaria	++++
4	„	++++
5	Lung cancer	+
6	Pleurisy with effusion	++++
7	Diaphragmatic pleurisy	+
8	Asthma	++
9	Diabetic coma	+++
10	Cancer of stomach (liver not involved) ..	+
11	Nephritis and haemolytic anaemia due to sulphonamide therapy	++
12	Rheumatoid arthritis	++++
13	„ „	++++

Table II shows that the patients who had positive reactions suffered from very varied conditions; in 10 cases the reaction was strongly positive, whereas in 3 the degree of flocculation was slight. In most instances it is difficult to explain why positive reactions were obtained; in Cases 9 (diabetic coma) and 11 (nephritis with jaundice) it is not improbable that it should have been positive. Further liver function tests were carried out in many of the patients (Nos. 1, 2, 3, 4, 10, 11, 12, and 13), but revealed no evidence of hepatic inefficiency. Most patients were dismissed when the primary disease was cured without repetition of the test, but in Cases 1, 2, and 3 the reaction became negative before dismissal. In Cases 12 and 13 the test was carried out on numerous occasions and positive reactions were always obtained. Repeated biochemical investigations failed to show any evidence of hepatic disease in these two patients, and the cause for the positive flocculation could not be explained.

(3) Sera of Those with Hepatic or Biliary Disease

The majority of patients in this group were suffering from hepatitis—the test being performed either during the acute course of illness or in convalescence—or from biliary obstruction. A small number of patients suffering from cirrhosis or cancer of the liver are included because of the variable results of the test so far reported in these conditions. Lastly, the results obtained in 12 patients who developed jaundice during the course of arsenical treatment for syphilis are included in order that some light may be shed on the nature of the jaundice.

(*a*) *Infective Hepatitis.*—The sera of 38 patients suffering from infective hepatitis were studied. Twenty-six came under observation early in the course of the disease, and in several cases readings were obtained during the illness; in 12 other patients the test was performed after recovery from an acute attack, such patients reporting in convalescence.

Table III.—*Cephalin-Cholesterol Flocculation Test in Acute Infective Hepatitis*

14	26/8/43 21/4/44 7/6/44 6/7/44 24/7/44	+ ++ + + ++++			

In every case of acute infective hepatitis the test was positive; in all but 7 cases it was markedly positive. The test is therefore a sensitive one in the detection of parenchymatous liver disease, for in a few patients the symptoms were mild and the degree of jaundice was slight, yet positive results were obtained. A further important use of the test, previously stressed, is its value in prognosis. This is illustrated by Table IV, which shows the results obtained during the course of the illness in patients observed during the acute stage.

It was found that the results of the cephalin–cholesterol flocculation test run parallel with the clinical severity of the disease and with other tests of hepatic function (serum bilrubin, laevulose-tolerance test, and hippuric acid synthesis test); with severe hepatitis, flocculation was most pronounced. Patients Nos. 14, 15, 18, and 19 died. In Cases 15 and 19, 4-plus readings were present throughout the illness, while in Cases 14 and 18 the test remained positive for a considerable time, and before death 4-plus reactions were recorded. In the 12 patients who had recovered from jaundice the test was negative in 10 and positive in only 2. These two patients clinically had a fairly severe attack of hepatitis, and although other tests showed liver function to be within normal limits the cephalin–cholesterol flocculation test was still positive.

(*b*) *Obstructive Jaundice*.—Fifteen patients were included in this group; the nature of the obstruction, the reason for this diagnosis, and the results of the tests are shown in Table V. In several cases the test was repeated but no change in the degree of flocculation was noted, so only this is included

TABLE V.—*Cephalin–Cholesterol Flocculation Test in Obstructive Jaundice*

Case	Nature of Obstruction	Reason for Diagnosis	Degree of Flocculation
39	Cancer of bile duct	Operation	—
40	Gall-stones	”	—
41	Cancer of pancreas	Clinical	—
42	” ” ”	”	++++
43	” ” bile duct	Necropsy	—
44	” ” ” ”	”	—
45	” ” pancreas	Operation	—
46	” ” bile duct	Necropsy	—
47	” ” pancreas	Operation	—
48	Gall-stones	”	—
49	”	”	—
50	”	Clinical	—
51	Cancer of pancreas	Operation	—
52	Gall-stones	Clinical	—
53	Post-operative stricture of common bile duct	Operation	—

Only one of the 15 patients in this group gave a positive reaction; in this case, unfortunately, the diagnosis rested solely on clinical examination, which, however, was fairly conclusive. The jaundice was of long duration and there was undoubted damage to liver cells. This patient died in his own home soon after dismissal.

(*c*) *Cirrhosis of Liver; Cancer of Liver*.—It is often difficult to be sure of the diagnosis of hepatic cirrhosis, but in the 9 cases in this group the diagnosis seemed fairly certain clinically or was confirmed by biopsy; in all 9 patients other liver function tests had indicated hepatic inefficiency. In 3 of the cases the test was positive, in 2 strongly so. In 3 patients with secondary cancer of the liver (confirmed in two by necropsy) the test was negative. In 2 other patients, in whom the diagnosis of cancer of the liver was made on clinical grounds, a 2-plus reaction was obtained in one case and a negative result in the other. Both cases showed evidence of hepatic inefficiency as judged by other liver function tests.

(*d*) *Arsenical Hepatitis*.—The test was performed in 12 patients who developed jaundice during the arsenical treatment of syphilis. The present paper does not permit of a full analysis of these arsenical jaundice cases, such as the relationship of the jaundice to the course of arsenical, its duration, and the presence of other toxic manifestations of arsenic. Of the 12 sera examined 7 gave a positive result, 5 of them strongly positive; in the other 5 cases there was no flocculation.

Discussion

The results obtained agree very closely with those of American workers. In normal healthy individuals the test is always negative when read at 24 hours. The tests were also read at 48 hours, when 13% of normal healthy individuals gave a positive reaction (1-plus or 2-plus). In carrying out this test it is therefore necessary to read the degree of flocculation after 24 hours. With the same cephalin reagent the test was carried out in normal individuals at two different periods separated by 4 months, and there was no significant difference in the number of positive reactions obtained at these times. The degree of ripening of the cephalin appears to have no great influence on the sensitivity of the reagent.

In the patients who suffered from conditions not primarily hepatic the positive results are difficult to explain; such patients did not fall into any special category of illness. A fairly complete biochemical analysis of many of these cases was carried out (serum bilirubin, laevulose-tolerance test, hippuric acid test, plasma proteins, N.P.N., and cholesterol), yet no explanation of positive flocculation could be found. In such patients the liver involvement is an incident in the primary disease, and it is only in biliary obstruction that difficulties in the interpretation of the test are likely to arise, but these can usually be eliminated by other means.

In acute infective hepatitis the test was positive in 100% of the cases. The degree of flocculation bears a definite relation to the severity of the illness. In severe cases of hepatitis 4-plus reactions were always obtained; a lessening in the degree of flocculation was a good prognostic sign, while a continued 4-plus reaction was often associated with death. The speed at which flocculation occurred also paralleled the severity of the disease; in two patients who died flocculation was noted as early as two hours after setting up the test. In convalescence the disappearance of flocculation should be hoped for; a continued positive reaction in two fairly severe cases suggested that there was residual liver damage.

In contrast with the positive flocculation always obtained in infective hepatitis, only one case (6.6%) of obstructive jaundice gave a positive result, and in this patient the jaundice was of long duration. Obstructive jaundice which is likely to be relieved by operation is nearly always associated with negative flocculation. The cephalin–cholesterol flocculation test is therefore of considerable value in the differentiation of these two types of jaundice; it was much more helpful than the van den Bergh test, the laevulose-tolerance test, or the hippuric acid synthesis test.

The cephalin–cholesterol flocculation test seems to offer much less help in patients suffering from cirrhosis or cancer of the liver than in jaundice due to acute infective hepatitis or obstruction of the biliary passages. In cirrhosis the reaction was stated by Hanger (1939) to parallel the activity of the pathological process. If a negative result is obtained then residual scarring would appear to be the sole pathological lesion. In metastatic cancer negative flocculation is usually encountered unless the process is severe, while in primary cancer positive results are usually obtained.

The results of the test in cases of arsenical jaundice are interesting. They agree closely with those of Hanger and Gutman (1940), and suggest that the icterus which follows the administration of an arsenical is not always due to parenchymatous damage, but may be caused by an obstructive process within the biliary passages. It is clear that the jaundice which develops in such patients differs from that of infective hepatitis. The cephalin–cholesterol flocculation test would therefore be of no value as the routine test in the early detection of liver damage in patients receiving arsenical treatment for syphilis.

Summary

The cephalin–cholesterol flocculation test is an entirely empirical reaction, but is simply carried out and appears to be of value as a test of hepatic efficiency.

Positive flocculation occurs in the presence of parenchymatous disease of the liver, and the degree of flocculation runs parallel with the severity of the case. A persistently positive flocculation is an unfavourable sign.

The test is of value in the differentiation of jaundice due to infective hepatitis from that due to biliary obstruction.

It is useless as a test in the early detection of liver damage in arsenical jaundice.

The test is positive in a small number of patients whose illnesses are not known to affect the liver; in normal healthy individuals, however, it is always negative.

From my experience the test is of definite value, even although ts mechanism is not understood.

I wish to thank Prof. J. W. McNee for his helpful advice and riticism, and Dr. J. B. Rennie for the results of other liver-function ests in the cases under review.

EMPLOYMENT OF THE POST-NATAL WOMAN

BY

J. V. O'SULLIVAN, M.D., M.A.O., F.R.C.O.G., F.R.C.S., M.R.C.P,

Obstetric Surgeon, City of London Maternity, Queen Mary's, and Bearsted Memorial Hospitals; Obstetric and Gynaecological Surgeon, Kingston County Hospital

AND

L. B. BOURNE, M.R.C.S., L.R.C.P., D.A.

Medical Officer, Messrs. A. C. Cossor Ltd., Highbury

It seemed proper that, as a sequel to our article on "Employment of Pregnant Women in Industry" (*Journal*, 1944, **1**, 108), we should follow these cases up and show how the women return to work after their confinements. We have done this in the 90 cases of the original article, and 40 others, up to 17 months after delivery.

Return to Work after Confinement

In our last follow-up of the original patients, in Feb., 1944, only 61 of the 90 mothers could be communicated with owing to change of address, evacuation, etc. The striking fact was that only 14 out of the 61 had returned to work at all, and only 4 at the end of four months after delivery. Two returned one month after the baby was born: one of these, a multipara with several children, had to do so for financial reasons, and her own mother looked after the baby. The other had a stillborn child. Two returned at two months: one of these was a single girl whose baby had been adopted; the other had lost her baby at birth. Four returned at three months. One of these had a premature stillbirth, the second arranged for the baby to be looked after by a neighbour, the third had her baby cared for by her mother, and the fourth took her baby to a day nursery. One returned at four months, her baby being cared for at a day nursery. Two returned at five months, their babies being in the care of relatives. One returned at six months, but did not continue, as the baby fretted in her absence. Two returned at ten months, giving no reason.

Thirty-six mothers preferred to stay at home. Fifteen said that they found the housework plus caring for the baby as much as they could manage. Three stayed at home because their husbands wished them to do so. Two said they would not trust their babies to anyone else. Two mothers were evacuated because of the air raids. Two did not feel well enough to return to work. Nine mothers said they would return to work if they had somebody to care for the babies, who were all under 1 year and could not, as a rule, be accepted by local day nurseries. Eight women gave no reasons for not returning to work.

In addition to the original 90 cases we have attempted to follow up 40 other mothers who attended our clinic. Through the difficulties previously noted, we were not able to contact more than 22, and only 4 of these had returned to work. One of them lost her baby at two months and then started work; the second started work at six months, the third—a single girl—at four months, and the fourth at nine months. We analysed the reasons why patients did or did not return to work, and the following is a summary of their replies.

Fifteen stated that, with the care of the baby and housework, they had too much to do. Two said their housework and caring for the baby were as onerous as factory work. One mother stated that she found the housework and baby even more tiring than factory work when she was pregnant. Eight mothers visited the clinic only for post-natal examination. Of these six were normal, one had a relaxed outlet, and one fairly severe haemorrhoids.

The medical officers of health of five boroughs in which the patients lived gave the following rules as to the permitted age of entry of babies to their day nurseries:

A. Not under 6 months.
B. From birth to 5 years. Under 3 months only in very special circumstances.
C. One year and over.
D. No minimum age limit, but very young babies accepted only under special circumstances.
E. Not under 6 months except in special circumstances—i.e., unmarried mother, etc.

There appears to be no uniformity locally, and we infer that this may be general throughout the country, although the Ministry of Health issues general recommendations.

The Position in the United States

In a personal communication to one of us (L. B. B.) Dr. Barbara Hewell, Acting Director, Division of Research in Child Development, U.S. Department of Labor, made some interesting observations on the situation in America which are worth recording. Her Department has suggested that women be granted at least two months' leave ordinarily, and longer if parturition or a post-partum period has been in any way complicated (*Standards for Maternity Care and Employment of Mothers in Industry*, U.S. Department of Labor, July, 1942). As most American employers have little or no experience of female labour there is considerable variation in or complete absence of policies in different industries on the subject of maternity leave. There has been no development, on anything like the national scale we have in Great Britain, of nurseries to care for children under 2 years of age of mothers working in war industries. However, centres have been set up for the group care of children from 2 to 5 years of age and also of school age. Federal funds have been made available to communities up to approximately 60% of the cost. There has been some supervision of these by State, Health, Welfare, and Education Departments in the different States.

"The policy of the Children's Bureau is strongly against the development of group care for children under 2 years of age. They feel that the young infant needs the continuous affection and consistent care of his own mother for his best emotional, physical, and mental development. There is no adequate substitute for a mother's care or for the care of some one person who holds this relationship to the child. Regardless of how good a group centre may be as to plant, hygienic conditions, number and training of staff, there remain the danger of communicable diseases when young babies are in groups, and the strong probability that the care cannot be as individual in type, and may not meet the emotional and developmental needs of the young infant.

The man-power situation in this country has not been so urgent that mothers of young children under 2 are essential in industry. It is realized, of course, that some mothers of young babies must work. When substitute care is necessary, the Children's Bureau advises foster-home care for children under 2, as more likely to meet the needs of the individual child. This type of care—both full-time for dependent or neglected children and day-time for children of working mothers—has been considerably developed in this country. This programme is under the supervision of child-welfare agencies whose trained workers approve the homes and the qualifications of foster-parents to care for children, and who give continuing supervision of the child in the foster home, working with both the employed mother and foster-home mother for the best interests of the child. The foster home should be near the child's home, caring for only a few children, and should duplicate home life as much as possible. The working mother pays the foster mother for this care.

There are scattered day nurseries in local communities where young infants receive care under private agency auspices, but this is not an extensive development. Many mothers, of course, make their own arrangements as to care of the children."

The following quotation from an interesting paper by Dr. Charlotte Silverman (U.S. Department of Labor) gives an account of her investigation of the problem:

"*Post-natal Leave of Absence.*—Most of the establishments that did not actually discharge employees on account of pregnancy stipulated that those who were required to take leave of absence remain away from employment for a specified period. Most of the plants set 6 weeks or 2 months as the required post-natal leave; one set it at 4 weeks, one at 4 months, and one at 6 months. Eleven required the amount of post-natal leave to be decided by a physician (the plant physician or the woman's own physician).

Extent of Return to Work After Delivery.—It was very difficult to find out how many women returned to work after childbirth. Most firms did not keep records of this type. Companies that had been employing women for many years, although they did not keep records of the number of returns, frequently were able to offer estimates. The textile mills had a very high percentage of returns. Some electrical plants also had a high percentage.

Reinstatement and Seniority.—Among the establishments that had high percentages of returns to work the question of reinstatement and seniority was probably a factor in motivating an early return. In several of these plants reinstatement and seniority privileges were effective for only 2 to 3 months after childbirth. If the period in which these privileges were effective were lengthened, women might be inclined to take longer post-natal leave."

Some British Statistics

An investigation on employment of women in industry before and after childbirth in this country carried out during 1940–2 by the Industrial Welfare Society gives the following general information. Twenty-six firms were approached; they all permit a return to work, but the period after pregnancy varies as follows:

At a minimum of 4 weeks	2 firms
" " 5 "	3 "
" " 6 "	6 "
" " 8 "	7 "
" " 12 "	4 "
On application at any time	1 firm
At any time a vacancy occurs	1 "
When fit to return	1 "
Left to opinion of welfare officer	1 "

The statistics of 29 firms who keep records of their pregnant workers gave the following figures:

Firm	Pregnancies	Returned to Work
A	12	1
B	20	2
C	37	1
D	11	2
E	50	1
F	13	10

One firm commented: "The great difficulty of mothers returning to work is the lack of day nurseries. The unmarried mothers, unless they have sympathetic parents, are forced to have their babies adopted, often against their will. Many married women would like to return to work if there were facilities for these very young babies." Another stated: "Two girls returned to work after one month—both through financial difficulties." None of the firms quoted had an antenatal clinic of their own.

Summary of Conclusions

Surprisingly few mothers return to work after confinement. In our own series only 18 out of 83 had returned to any work, excluding housewife duties, up to 17 months after confinement.

Death of the baby or financial matters were the main reasons given for the return to paid employment.

From our experience of the normal working mother we conclude that six months is a reasonable time after pregnancy for return to work to be considered.

We are grateful to Mr. R. R. Hyde of the Industrial Welfare Society, Dr. Katherine Bain, and Dr. Barbara Ann Hewell of the Children's Bureau, U.S. Department of Labor, for their co-operation, and to Sister Harwood of our own works antenatal clinic.

S. Solomon, M. Kaslik, and N. Kiven (*Ann. intern. Med.*, 1944, **21**, 639) record three cases of periarteritis nodosa in which the condition was diagnosed during life and confirmed at necropsy. The diagnosis should be considered in patients with prolonged fever of unknown origin who have irregular or baffling symptoms referable to many parts of the body. A biopsy will usually reveal characteristic changes in the smaller arteries. The disease is probably an allergic reaction to many different antigens. There is no specific treatment.

Medical Memoranda

A Diagnostic Problem: An Unusual Case of Hepatitis

The following case is interesting in view of the prevalence o hepatitis. A girl aged 13 months was admitted to the hospita on Sept. 6 as a case of notified cerebrospinal fever (post-basic). Except for occasional "snuffles" the history disclosed nothin abnormal until two weeks before admission. She was the said to have had an attack of bronchopneumonia, treated fo four days with 8 g. of sulphathiazole. Subsequently the chil had been fretful, and for two days before admission there ha been neck rigidity, head retraction, and persistent vomiting.

CLINICAL HISTORY

On examination the child's condition seemed satisfactory—T. 97°, P. 120, R. 26—but she was irritable and had a stiff neck wit head retraction; Kernig's sign and Brudzinski's reflexes were negative. The gums were inflamed owing to teething, and the liver wa palpable two fingerbreadths below the right costal margin, the uppe limit of superficial dullness being percussed at the fifth interspace Lumbar puncture was performed. The fluid was clear and unde normal pressure, and contained "2 leucocytes per c.mm., protei 10 mg., globulin 0, chlorides 770 mg., sugar rather in excess. W.R negative."

During the next three days the (presumable) meningism disappeared and vomiting ceased. The stools remained norma throughout the illness, while the urine contained a trace of albumin On Sept. 10 a swelling appeared in the right renal angle. It wa hard, deep-seated, immobile, but not attached to adjacent bon structures, and was associated with slight oedema of the overlyin skin. On Sept. 11 the lump was larger and softer, but its natur remained obscure. At 4.30 p.m. precisely that afternoon the chil screamed violently, became cyanosed, and appeared to be in pain On examination her colour was ghastly, her extremities cold, puls impalpable, temperature subnormal, and respirations about 80 pe minute. She was gravely ill, and the dramatic suddenness of th change suggested a catastrophe such as an internal haemorrhage o spontaneous pneumothorax. No thoracic signs were elicited, but th liver was over five fingerbreadths below the right costal margin while the upper limit of superficial dullness was level with the sixt rib on percussion.

Surgical advice was sought, and Mr. Kennedy of Plymouth kindl saw the child. Nevertheless, no diagnosis was made, and the onl course available was treatment for shock on the usual lines. B 8.30 p.m. her condition had improved slightly—T. 98.4°, P. ?160 R. 88—and the liver was only three fingerbreadths below the costa margin, but at 10.35 p.m. she collapsed and died, her malad undiagnosed.

POST-MORTEM EXAMINATION

The necropsy was performed by Dr. M. R. Thomas, with the kin permission of Dr. Wordley. Externally there were no distinctiv marks and the lumbar swelling noted during life had disappeared About half a pint of haemorrhagic fluid was found in the righ pleural cavity. Otherwise, apart from petechial haemorrhages o the serous surfaces and a small pericardial effusion, the heart an lungs seemed normal. In the abdomen half a pint of bile-staine ascites was found. The liver was tremendously enlarged an engorged, and the cut surface was yellow. The hepatic artery an biliary system appeared normal, as also the duodenum and othe viscera, though the right kidney was displaced backward into th loin by the enlarged liver, thus accounting for the mysterious lumba swelling.

Histologically, the liver showed generalized parenchymatou necrosis, particularly marked in the portal zones. There was neithe hyperplasia of liver cells nor bile-duct proliferation. The organ wa stained and examined for spirochaetes, but none was seen, nor wa evidence of syphilis found. Other organs showed no special change except scattered petechial haemorrhages.

DISCUSSION

It is unfortunate that investigations, including blood count and urine analysis, were not done, but precise indications wer wanting until too late. First, the cause of the meningism remains obscure. It might have been due to the hepatic lesio or even to "teething." It should be remembered that occasionally meningism is a marked feature of intolerance to su phonamide therapy, particularly in cerebrospinal fever—a highl improbable cause in this instance, however, eight days late Alternatively Weil's disease with a meningeal onset merits consideration, but it is unlikely that such a case would have bee apyrexial throughout, nor were any spirochaetes demonstrated

The puzzling lumbar swelling received satisfactory explanation at necropsy. More difficult of explanation was the sudde and catastrophic deterioration in the child's condition, wit apparent hepatic displacement and enlargement. The rapi accumulation of a haemorrhagic pleural effusion—singula indeed in respect of the complete absence of physical signs i the chest—was probably largely responsible. Sudden cardia ailure may also have aggravated the general condition and ncreased the size of the liver from acute passive congestion. No doubt the various effusions and petechial haemorrhages were direct consequences of hepatic failure.

In view of the extensive necrosis it is perhaps surprising that jaundice was completely absent. Either the liver destruction was too rapid or this was really an example of extreme atty degeneration of the organ following an acute infection —bronchopneumonia in this instance, as was stated in the hisory. The latter explanation, however, was not supported by the histological findings, but certainly the possibility of a fulminating virus hepatitis cannot be completely excluded.

Lastly, of drugs sulphathiazole alone was given, to a total of 8 g. two weeks before death. Fatal cases of hepatitis are nown to have followed sulphonamide therapy, and symptoms ave not always declared themselves until after the final withdrawal of the drug. Of all possible causes, this does seem he most feasible; but, unfortunately, the available evidence is nconclusive.

I am indebted to Dr. T. Peirson, medical officer of health for Plymouth, for ermission to publish this case; to Dr. D. F. Johnstone, medical superintendent f this hospital, for his interest in the preparation of the paper; and to r. M. R. Thomas for the post-mortem examination and preparation of stological material.

City Isolation Hospital, Plymouth.

Splenomegaly in Bacillary Dysentery

As we have not found a reference to splenomegaly in dysentery n the limited amount of medical literature which we have been ble to search we think the following account of a series of ases may be of interest.

A SERIES OF CASES IN THE MIDDLE EAST

Enlargement of the spleen was found in 50 (5.77%) out of a otal of 866 cases of bacillary dysentery admitted to a general ospital in the Middle East between Aug., 1943, and Jan., 1944. The cases had occurred regularly throughout this period. There was no evidence of the presence of any other disease which might have caused splenic enlargement. In none of the cases was there any lymphadenopathy or clinical evidence of anaemia. At least one blood slide was examined in each case, but no malaria parasites were discovered. Only four cases gave a istory of previous single attacks of malaria—10/12, 2, 3, and years previously. Three cases were not included in the series, as it was considered malaria might be the cause of the splenomegaly, two of the patients being Cingalese and the other a British "other rank" who gave a history of three attacks of malaria two years previously. Three other cases were excluded, n two of which the splenomegaly persisted for 21 and 28 days espectively, and in the third there was a history of two attacks f short-term fever in the previous two months. It seems nlikely that enteric fever could produce this almost constant icture of sudden onset of diarrhoea, associated with blood and mucus in the stools, fever for 2 to 3 days, absence of rose spots, and fitness for duty in 10 to 12 days.

Twenty of the patients had been in the Middle East for less han four months, and of these eight had been abroad for only our weeks or less. The cases were not confined to one partiular camp, but were admitted from various surrounding sites ver a wide area.

CLINICAL DETAILS

Except for the splenomegaly all the patients showed the sual clinical features of bacillary dysentery. They were of the mild or moderately severe type. The average duration of diarrhoea was 2.88 days (maximum 10 days; minimum 1 day— cases). The temperature on admission ranged from 99° to 02° in 38 cases, but in 12 there was no fever. Two cases were brile for 3 and 5 days respectively, but the remainder had normal temperature after 48 hours.

In 46 cases blood and mucus appeared in the stools; 23 ases on microscopy showed bacillary exudate and 27 cases definite exudate; 4 cases had liquid stools with mucus and howed indefinite exudate. Of 31 cases in which a culture was erformed 13 showed the Flexner bacillus (Flexner I, 3 cases; lexner II, 6 cases; undetermined, 4 cases) and 18 showed no athogens.

In 49 cases the spleen was palpable on the day of admission nd in one on the day after admission (3rd day of disease). n 37 cases the spleen on inspiration reached a point 1 fingerreadth below the costal margin, in 10 cases 2 fingerbreadths, nd in 3 cases 3 fingerbreadths. In 43 cases the spleen remained alpable for 2 to 6 days only, but in 7 cases the edge could st be felt on discharge from hospital on the 15th to 18th day disease. In one of these cases, which it was possible to review, the spleen was no longer palpable 3 months later. Total and differential white blood cell counts were carried out in 22 cases. No constant abnormality was present. The average total was 6,959 (maximum 15,300, minimum 3,200). The average proportion of polymorphonuclear leucocytes was 62%.

DISCUSSION

The cause of the splenic enlargement in these cases is not understood. As already stated, malaria, enteric group fevers, and other obvious causes of the splenomegaly were excluded. It is suggested that it is a non-specific phenomenon, and this is borne out by the fact that similar splenic enlargement was found to occur equally commonly in certain other infectious diseases in the Middle East (Illingworth, 1944, personal communication). Illingworth reported that splenic enlargement occurred in 6.3% of 221 cases of diphtheria seen by him, 5% of 81 cases of tonsillitis, 7.8% of 42 cases of scarlet fever, and 5.3% of 38 cases of measles. In only 4 of these cases was there a previous history of malaria and in no case was there any other discoverable cause for the splenomegaly. In all except one case the splenic enlargement had subsided within a fortnight of the onset of the infection. It is interesting that the frequency of splenomegaly in these infectious diseases was approximately the same as that of the cases of bacillary dysentery reported above.

We are indebted to Major R. S. Illingworth for his invaluable help and also to Lieut.-Col Bodley Scott for his criticism and advice. We should also like to thank Col. W. B. Stevenson, officer commanding a Middle East general hospital and Brig. W. K. Morrison, officiating D.M.S., M.E.F., for permission to publish this article.

Jaundice during Arsenotherapy

In view of the general interest taken in the causation of jaundice during arsenotherapy, it may be of value to record some observations made at the neurological clinic, Metropolitan Hospital, on a consecutive unselected series of 12 cases. These patients were all suffering from neurosyphilis; their ages ranged from 13 to 64 years. Treatment has consisted of intramuscular or subcutaneous injections of 3 c.cm. of acetylarsan (May and Baker), together with 0.5 c.cm. of intramuscular bismostab in courses of 10 to 12 injections, with intervals of one month. Potassium iodide orally was also given. By the use of this preparation of arsenic given by these routes over a period of 2 to 4 years, possible transference of minute quantities of serum from patient to patient, as suggested by Major Salaman (1944) to be a potential cause of jaundice, is avoided.

These patients were carefully observed while undergoing treatment, and it is significant that not a single case of jaundice occurred. This suggests that where the intramuscular or subcutaneous rather than the intravenous route is used there is little likelihood of jaundice occurring. This seems to be supporting evidence for the belief that the hepatitis which is sometimes produced during arsenotherapy is not a direct toxic effect due to the arsenic but is rather of an infective origin, as is now thought to be the case in homologous serum jaundice or in the jaundice occurring after yellow-fever vaccination. Particulars of the cases are as follows:

Case	Sex and Age	Disease	W.R.	Commencement of Arsenotherapy	No. of Courses	No. of Inj.
1	M 55	Meningo-vasc. syph.	+	Mar., 1941	4	10
2	M 13	Cong. G.P.I.	+	" "	5	12
3	F 49	A.R. pupils ? Syph. died out	−	" "	2	12
4	F 36	Meningo-vasc. syph.	+	Nov., 1941	5	12
5	F 36	Cong. tabes dorsalis	+	Nov., 1942	5	12
6	M 57	Meningo-vasc. syph.	+	Feb., 1942	5	12
7	F 33	G.P.I.	+	Apr., 1942	4	12
8	F 49	Tabes dorsalis	+	June, 1942	4	12
9	M 56	Meningo-vasc. syph.	+	Aug., 1942	4	12
10	F 36	Cong. tabes dorsalis	+	Nov., 1942	3	12
11	M 55	Taboparesis	+	June, 1943	3	12
12	M 41	"	+	Aug., 1943	3	10

Cases 2 and 7 received malaria therapy previously. All the above cases now have a negative Wassermann reaction.

I wish to thank Dr. Worster Drought and Dr. N. G. Hulbert for access to the case records, and the latter also for his kind help and advice.

Reviews

PARASITIC PROTOZOA OF MAN

Manual of Human Protozoa: With Special Reference to their Detection and Identification. By Richard R. Kudo, D.Sc. (Pp. 125; illustrated. $2.00 post paid or 11s.) Springfield and Baltimore: Charles C. Thomas; London: Baillière, Tindall and Cox. 1944.

This little book is likely to be of considerable value to those who are taking up for the first time the study of the parasitic protozoa of man. It gives clear and concise descriptions of the various protozoa, outlines of their life-histories, and the methods of their transmission, whether contaminative or inoculative. The illustrations, usually original, are for the most part excellent. That of *Trypanosoma gambiense* could be improved, for it does not depict the three forms which are characteristic of the group of polymorphic trypanosomes to which this type belongs. The same remark applies to the illustration of *T. rhodesiense,* though here the posterior nuclear forms are shown. On the subject of transmission of oriental sore the sandfly is rightly blamed, but the author appears not to be aware that there is equally strong evidence of the sandfly as a vector of kala-azar. In addition to the description noted above, chapters are devoted to the technique employed for detecting the protozoa of the digestive tract and those of the circulatory system. As culture methods are advocated for leishmania and trypanosomes, it would not have been out of place to refer to cultivation of the intestinal protozoa. There is a chapter on the coprozoic protozoa, which, developing in stale faeces, must not be confused with the forms parasitic in the intestine, while various extraneous objects which may occur in faeces and can lead to errors in diagnosis are noted. Similarly reference is made to objects which may contaminate blood films and be mistaken for malarial parasites or other organisms.

The book, which is beautifully got up, contains in a small space a great deal of useful information. Undoubtedly it will fulfil the author's hope that it will serve as a practical guide to those who contemplate the detection and identification of the human protozoa.

THE LIVING CELL

What is Life? The Physical Aspect of the Living Cell. By Erwin Schrödinger, Senior Professor at the Dublin Institute for Advanced Studies. (Pp. 91. 6s.) Cambridge: The University Press. 1944.

It is not long ago since the gulf between the living and the non-living was regarded as impassable, but now the increase of knowledge in the sciences of microbiology, chemistry, and physics makes it seem that the solution of the problem of making life in the laboratory only just eludes us. In these lectures, now presented in book form, a very distinguished physicist makes his contribution to that solution. First he points out that modern physics is largely statistical—that is, it deals with tendencies in very large numbers, though it is well known that individual units in these large groups behave very differently from the group as a whole. This may be illustrated by the random heat movements of units contrasted with the orderly movement of magnetism or the Brownian movements of an individual droplet in a uniformly sinking fog.

So far physical laws have applied to a periodic crystal, whereas the chromosome fibre, the most essential structure in a cell, may be of the nature of an aperiodic crystal, for which different laws must be invoked to explain its properties. The division of the chromosomes and the mutations on which heredity and evolution depend are next considered. The gene unit is probably a molecule—i.e., a relatively stable collection of a comparatively small number of atoms which only occasionally change their relationships (mutation). These changes may be compared to the quantum jump familiar in ordinary physics. Delbrech's model is discussed in relation to mutations, and it is suggested that the difference between living and non-living substances is that between negative and positive entropy, the living material absorbing orderliness (negative entropy) from the environment, thus delaying its decay with thermodynamical equilibrium (death). The power of absorbing orderliness seems to Dr. Schrödinger to depend on the presence of aperiodic solids, the chromosome molecules in living matter If this can be accepted it removes the pessimistic view of th physicist that the ultimate fate of the universe is to "ru down" into universal death.

To all who are philosophically inclined this little book wil prove fascinating, but the hard-boiled materialist will probabl be well advised to pass it by.

A RED INDIAN TRIBE

The Navaho Door. An Introduction to Navaho Life. By Alexander H. Leighton and Dorothea C. Leighton. Foreword by John Collier, Commissioner of Indian Affairs. (Pp. 149; illustrated. $4.00 or 22s. 6d.) Massachusetts: Harvard University Press; London: Oxford University Press. 1944.

There are some 370,000 Red Indians in the U.S.A., one hal full-blood and the other half mixed—chiefly with whites, som being negroid. There are 200 tribes speaking as man languages; but about 56,000 Indians know only their ow tongue. *The Navaho Door* deals with the tribe that occupie the Navaho Reservation—by far the largest of these settlements; it is in the south-west of the United States.

The authors of this book, Drs. A. and D. Leighton, under th aegis of the U.S. Indian Service, have studied this tribe fro social, cultural, medical, and psychiatric points of view Americans have made a world-wide specialty of cultura relationships, entailing much labour of concentrated though concerning the minds and bodies of the people they ar observing. They thereby gain experience in race tolerance an the source of future international peace. But with the purpos of bettering the faulty social characteristics of the Red Indian these people have been despoiled of all they had to offer—cheap labour and land.

The authors supply general information about the Navahos and, because they are both physicians, they devote a good dea of space to health problems, improvement of the ways th sick are handled in their homes, and the methods adopted t teach the benefits of early admission to hospital. Life-historie are given in detail in order to gain personal knowledge o how the Navahos view their lives in health and disease. Thoug the science of anthropology is dealt with in a rather cursor manner, the book is a close and interesting study of a nativ race living in an outpost of civilization. There are thirty-fou striking photographs to illustrate the text. The price ma however, lessen the wider circulation that this volume deserve

Notes on Books

One of the undertakings of the Charity Organization Society i the compilation of an *Annual Charities Register and Digest,* of whicl the 52nd edition, for 1945, has now been published by Longmans Green and Co. As in former years, this gives information abou the societies, associations, and other bodies that provide relief i affliction and distress of all kinds; it is in fact a classified registe of charities in or available for the Metropolis. There are 43 sections the last three dealing with special war organizations, hostels fo H.M. Forces, and refugees; there is also a full index. Copies (pric 10s. 6d.) may be had from the C.O.S., Denison House, Vauxha Bridge Road, S.W.1, or from the publishers.

For Childless Wives, by a doctor, is a simply and clearly writte pamphlet of 16 pages published for the Family Planning Associatio by H. K. Lewis and Co. Ltd. It is written for the benefit of steril couples so that they may know what the problem is and how it ca be tackled. Any practitioner who wants to give such informatio to his sterile patients will find this pamphlet the easiest way of doin it. As Lord Horder observes in a foreword, "There is a specia and a growing need to instruct husbands and wives as to the step they should take in respect of the wanted child which fails t arrive." An edition of this pamphlet for clinics and hospitals is t be sold at 6d.; the edition for the public is to be sold at 2s. Th work of the Family Planning Association depends on voluntar subscriptions, and presumably it is hoped that the sale of th pamphlet at the latter price will bring in money for the developme of clinics.

R. F. Watson, S. Rothbard, and H. F. Swift (*J. Amer. me Ass.,* 1944, **126,** 274) state that penicillin in doses ranging fro 1,975,000 to 3,470,000 Oxford units, given over a two-week perio to eight young adults with acute rheumatic fever, apparently faile to alter the course of the disease.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 10 1945

WAR SURGERY IN THE U.S.S.R.

"The Russian soldier is safe in the hands of the Russian surgeon": with these words Sir Ernest Rock Carling summarized the impression formed by British surgeons after their visit to the Soviet Union eighteen months ago. One of the features which most impressed the visitors from this country was the organization of military surgical services in the Red Army. In forward areas, up to a depth of 50 to 100 miles, treatment of the wounded is the responsibility of the chief surgeon of the Red Army Medical Corps, Colonel-General Smirnov—an alert, forceful, and vigorous young man whose contribution in this week's *Journal* emphasizes the reality with which his task has been faced and the success with which it has been accomplished. The Red Army surgeon is a soldier as well as a doctor; he recognizes that organization is "determined more by the military situation than by purely medical consideration"; he knows that his first task is "to return the maximum number of wounded to the ranks"; and he directs lightly wounded not to the usual lines of evacuation but to a special local hospital so that rapid return to the front line is assured. For the more seriously wounded, specialist treatment is provided not only in base hospitals but in forward zones. Within a few miles of the front line there is segregation of cerebral, facio-maxillary, thoracic, and orthopaedic cases. Such a plan is ideal. But the difficulty is at once apparent. How is it possible to provide the necessary number of specialist surgeons? General Smirnov gives two answers to this question. The first may be unavoidable, but it nevertheless has drawbacks: "Success in this respect has only been possible in accordance with a simple doctrine based on the following principle . . . a single school of thought with uniformity n methods of prophylaxis and treatment." Such uniformity s characteristic of Soviet Medicine. On reflection it is difficult to conceive how it could have been otherwise. Thirty years ago there were thirteen medical faculties for the whole of the vast continent of Russia; to-day no fewer than 25,000 doctors qualify every year. Is it possible that o vast a problem could have been solved in so short a ime without standardization and uniformity? Is it posible that a similar demand, created by the exigencies of war, could have been met without "a single school of thought"? It is noteworthy that this solution has also been adopted by the medical services of the United States Army, so that, for example, every fracture of the shaft of the humerus sustained by an American soldier in Europe s treated, in accordance with directions from Washington, by skeletal traction from the olecranon. But let it be emembered that surgical standardization is a special solution of a special problem. As Watson-Jones recently maintained in discussing the orthopaedic service of the Royal Air Force: "Central dictation of technique is the easy method of assuring a uniformly high standard, but from the point of view of surgical progress it is the pernicious method." The second answer given by General Smirnov to the problem of rapid development of specialist services is one that might be expected from a young and virile organization which can appoint as its chief surgeon a man who has not yet reached the age of 40: "The whole Red Army Medical Corps, from general to private, is being systematically trained. It is studying the new experiences which have been gained. . . . The Red Army medical service does not stand still." This is the triumph of youth —a triumph which is engaged not so much in recording the successes of the past as in facing the problems of the present and the future.

After treatment in forward areas the wounded of the Red Army are evacuated to civilian hospitals in the rear under the direction of the Commissar of Health, assisted among others by Prof. Priorov, chief surgeon of the R.S.F.S.R. and director of the Moscow Institute of Traumatology and Orthopaedics, and Dr. Kotov, director of the Ukrainian Institute of Orthopaedics and Traumatology in Kharkov, both of whom contribute articles to this week's *Journal*. These two surgeons have honoured us by their visit to this country, and have commanded the respect and esteem of every British surgeon with whom they have come into contact. Our sympathy goes out to Prof. Priorov, whose knowledge of Britain has been amplified by long residence in a nursing home, recovering from a serious operation. We can wish no more for him than he claims for the victims of amputation: "Only work can complete their rehabilitation; only work can heal their severe psychic wounds and restore their shaken nerves." These are the ideals we also have set ourselves. Rehabilitation through work is the purpose of our Disabled Persons (Employment) Bill. The problems of treatment of the war disabled in the Soviet Union and in Britain are the same; we are dealing with them in the same way. We can learn from each other.

At this moment we may look with admiration at the way the medical organization of the Red Army is standing up to the immense strain imposed on it by the tremendous onslaught of the Russian Marshals on the Eastern Front. At such a time it is a privilege to be able to publish in these columns articles by Russian surgeons which afford the British reader a glimpse at their problems and at the way they set about solving them.

THE POWER OF THE PURSE

Medical men and women will read with interest a reply given by Mr. Willink in the House of Commons on Jan. 18 to a question on the Goodenough Report on Medical Education.[1] He said that the Government, recognizing the importance of medical education and research, had accepted the principle of increased grants for these purposes to be distributed by the University Grants Committee, through universities to medical schools, postgraduate schools, and institutions and hospitals used for teaching and research. The Government shared the views of the report "on the importance of affording to women equal opportunities to those enjoyed by men for medical training and for obtaining postgraduate experience." It has therefore decided that the payment of grants to medical schools will depend upon whether or not they adopt the principle of admitting a "reasonable proportion" of students of both sexes. There is logic in this situation which even the most hardened antifeminist must accept. If the country needs doctors, as it does, and needs women doctors also, as it does, then the Government can hardly be expected to make an exclusive subsidy for male students. All the same, educationists, looking at education from the wider standpoint, may wonder whether it is wise generally to enforce co-education by the threat of the purse.

---

[1] *British Medical Journal*, Jan. 27, 1945, p. 136.

But when we read in the same reply that the Minister is using the same threat in what seems to be an attempt to arrogate to himself powers belonging constitutionally to another body we may well feel alarmed. "The Government," it is stated, "attach equal importance to the revision of the medical curriculum, and acceptance of the principle of increased grants for medical education and research is dependent on the early completion of this process." Having delivered this edict, Mr. Willink adds that the Government is "glad to learn that, as recommended by the [Goodenough] Committee, the G.M.C. has already taken the initiative in the matter." Unless we have misread this statement of Government policy it appears that, through its Ministry of Health, the Government is doing two things. It is first of all threatening to withhold money from medical schools, who are not responsible for revising the medical curriculum, unless the curriculum is revised by licensing bodies, who are responsible for any such revision (it insists on "early completion"). The Government is, in fact, using the power of the purse to coerce those responsible for teaching medical students. Secondly, it is abrogating the functions of the G.M.C. and, by implication, is questioning its efficiency in maintaining standards of medical education.

The Goodenough report is a significant, if rather verbose, contribution to the subject of medical education. The Royal College of Physicians recently published an equally authoritative and more succinct report on the same subject. The B.M.A., too, was early in the field, with a sane pronouncement on the eternal theme of medical education. From these and other sources those responsible for medical education will seek inspiration and will weigh in the balance the findings and recommendations of the Goodenough as of other committees. But is it the intention of the Ministry of Health to try to enforce revision of the curriculum on the strength of the conclusions reached by a committee of its own choosing? And is it to do this by the rather vulgar trick of withholding money meant for education and research? Has the Minister of Health forgotten that the responsibility for maintaining standards of medical education lies with the General Council of Medical Education and Registration, to give the G.M.C. its full title? The G.M.C. is a statutory body set up by the Medical Act of 1858. It maintains standards of medical education by indicating to licensing bodies in the form of recommendations what it will regard as an adequate minimum curriculum, and by satisfying itself, through inquiry, visitation, and inspection, that no particular curriculum is in this sense inadequate. If it is not so satisfied it may make representations to the Privy Council, which, on review of all the evidence, may suspend the right of a licensing body to qualify men to practise. This provides a check to hasty and ill-considered action. If the G.M.C. defaults in its duties the Privy Council may require it to mend its ways, and indeed may exercise the powers of the G.M.C. if it does not do so. There seems to be no call for this latest intervention of the Ministry of Health in a matter in which the constitutional responsibility of "the Government" has rested primarily, ever since a *Medical Register* was first compiled, with the Lord President of the Council as the Ministerial head of the Privy Council Office.

BAROTRAUMA

Experimental observations by Armstrong and Heim[1] on five healthy men are the foundation of accurate knowledge of the physiology of the Eustachian tube in aviation, though the work was published only seven years ago. These men were subjected to changing rates of pressure varying from 5.4 mm. to 27 mm. of mercury per minute, corresponding to 200 ft. to 1,000 ft. of altitude per minute, through ranges of pressure from 141 mm. to 760 mm. of mercury, corresponding to 0 ft. to 40,000 ft. in altitude. By decreasing the pressure from sea level (760 mm.) at a constant rate it was found that a change of 3 to 5 mm. of mercury, corresponding to 110 to 180 ft. in altitude, was required to produce any effect. The discomfort increased until at 15 mm. of mercury, or 500 ft. in altitude, an involuntary click was felt in the ears and the sensation of fullness was relieved. Succeeding clicks occurred at intervals of 11.45 mm. of mercury, or 435 ft. of altitude, the succeeding clicks during ascent corresponding rather to change in altitude than to identical differences in rarefaction: tha is to say, that during ascent the Eustachian tubes open involuntarily and equalize the pressure in the tympanum with that in the atmosphere outside. In descent, however the effect of changing pressure is different. The Eustachian tubes remained closed under all degrees of pressure, and finally the tympanic membrane ruptured unless the tube were opened by the act of swallowing, which become impossible when a negative pressure of 80 to 90 mm. o mercury is produced in the middle ear. Frequent voluntary acts of swallowing are necessary, therefore, to maintain pressure equilibrium. The effect on the middle ea was called acute aero-otitis media, and the discomfort and deafness from the retraction and stretching of the tympanic membrane caused by repeated exposure to this form o injury were symptoms of a chronic form. There is, however, no inflammatory change, unless it be a secondary effect of the injury, and therefore in the interests alike o accuracy and euphony the term otitic barotrauma has now taken its place and has been adopted by the R.A.F.

Since then barotrauma has played an important part i the problem of maintaining the fitness and efficiency o air crews, and the effects have been studied both clinicall and in a decompression chamber designed for the purpose. Pain, deafness, tinnitus, and occasionally vertig are the symptoms, naturally of varying degree, and are relieved as soon as the pressure equilibrium is restored by swallowing, by Valsalva's experiment, politzerization or even Eustachian catheterization, or by re-ascent. Objective physical signs may be scarcely seen, but varying degrees of congestion of the tympanic membrane and middle ear may be observed, as shown in some beautiful coloured plates from drawings by McGibbon.[2] Haemorrhages, effusion into the middle ear, and even rupture of the membrane may occur. Although the prognosis is good the condition is common and temporarily disabling, not only to the individual but, as R. M. S. Matthews[3] has emphasized in this *Journal*, also to the crew of which he is a member if he should be rendered unable to go into action even for one day. The cardinal factor in the production of barotrauma is obviously Eustachian obstruction, which may be of a degree sufficient to cause only trivial or negligible symptoms at ground level, but enough to prevent free ventilation at changing altitudes, especially rapid descent, and so cause barotrauma. Ordinary clinical examination and testing in the decompression chamber will suffice to eliminate a number of those particularly liable to develop acute barotrauma, estimated by Dickson[4] at 8.9%. Any measures which will lower the incidence of infectious coryza are important in eliminating acute Eustachian catarrh, and some responsibility must rest on the medical officer in making the decision whether a member of an air crew may or may not fly if he has a cold in the head. It may be added that similar considerations apply to the accessory sinuses of the nose, for, although they possess no such active mechanism as does the Eustachian tube, changes of pressure may cause acute and disabling pain if the ostium, particularly of the frontal sinus, becomes obstructed.

THE B VITAMINS AND HARD WORK

It has often been stated that diets very deficient in vitamin B will cause serious physical and psychological deterioration after a few days' hard work. In their studies on induced vitamin B_1 deficiency in human volunteers R. D. Williams and his collaborators[5] reported a syndrome closely resembling that of neurasthenia: muscular atony and tenderness, nausea, vomiting, faint heart sounds, changes in the electrocardiogram, tachycardia, lowered blood pressure, apathy, photophobia, anorexia, abdominal distension, paraesthesiae, and fatigue. Psychological disturbances included depression, fear, irritability, inattention to details, confusion of thought and memory, headache, insomnia, tenseness, intolerance of noise, and increased sensitivity to painful stimuli. These manifestations, however, appeared only after prolonged vitamin B_1 deficiency, and the subjects of the test did not perform heavy work. Similar observations were reported by other workers.[6] [7] Jolliffe[6] reported deficiency symptoms—anorexia, dyspnoea on exertion, precordial pain, palpitation, and fatigue—as early as the third day in subjects on a diet poor in vitamin B_1. Johnson and his colleagues[8] subjected ten volunteers to hard physical work on diets deficient in the vitamin B complex and reported fatigue, deterioration in physical fitness, muscle pains, and poor appetite after a few days. Egaña and others[9] made similar observations on men doing manual labour. Barborka, Foltz, and Ivy[10] also noted that diets poor in vitamin B and riboflavin produced symptoms of easy fatigue, irritability, anorexia, and pains in the leg in men doing active physical work. More recently Archdeacon and Murlin[11] observed that muscular endurance is greatly decreased on a diet low in the vitamin B complex and providing only 0.27 mg. of vitamin B_1 daily.

These observations, which have been generally accepted, are now challenged by Keys and his co-workers,[12] who claim that they were not made under sufficiently controlled conditions. They kept eight men doing severe and exhausting physical work for 14 days on a diet providing only 0.16 mg. of vitamin B_1, 0.15 mg. of riboflavin, and 1.8 mg. of nicotinic acid per 1,000 calories daily—less than a third of the computed daily requirements of subjects performing heavy work. Comprehensive clinical examinations, psychological tests, and objective tests covering endurance, anaerobic work, speed, co-ordination, and muscle strength failed to show any significant changes in the subjects on the diet. The men were admittedly rather stiff and sore, but this was attributed to hard work on the treadmill. There were no significant changes in blood lactate and pyruvate, which are said to rise in subjects doing heavy work on diets deficient in vitamin B_1. Keys and his co-workers attribute the subjective symptoms described by Jolliffe, Johnson, and others to suggestion, as they are of the vague type commonly associated with the neurotic patient. They also criticize the conditions of experiment: a group of sedentary laboratory workers, conditioned to expect certain effects, were suddenly put to unaccustomed physical work and given a peculiar and monotonous diet. In other words, certain results were anticipated and obtained. In the test devised by Keys the subjects spent a control period of three weeks performing heavy physical work on a controlled standard diet. Then they were given the deficient diet while performing the same heavy work. Further investigation is plainly needed to reconcile these contradictory observations, particularly in view of the recent statements that biosynthesis of vitamin B_1, riboflavin, and nicotinic acid may occur in the human intestine,[13-15] and so complicate all human experimental work with these vitamins.

SHOCK THERAPY AND CONDITIONED REFLEXES

While the beneficial results of shock therapy in schizophrenia are widely accepted, the way that treatment works has remained a mystery. The hypothesis of von Meduna[16] was that, since epilepsy is rarely observed in patients with psychosis, the subjection of psychotic patients to epileptoid convulsions might improve the psychosis. But what do we know of the effect of convulsions on the nervous system? Some interesting results have lately been obtained by E. Gellhorn.[17] With Darrow[18] he first studied the action of leptazol on the systems of the cat which are innervated by the autonomic. They demonstrated that leptazol not only caused convulsions but had other effects which could be observed when the convulsions were prevented by curare. Thus leptazol caused a fall of blood pressure, a dilatation of the pupil, a contraction of the nictitating membrane, and increased sweating. More important than these immediate effects was that for some hours after convulsions had been induced sympathetic reflexes were elicited more readily than before; thus the dilatation of the pupil on stimulating the brachial plexus was increased. They therefore concluded that one effect of leptazol was to heighten the reflex excitability of sympathetic centres.

More impressive, however, is Gellhorn's[17] recent work on conditioned reflexes. He placed a rat in a cage divided into two parts by a low partition over which it could jump. An electric current was passed through the floor on which the rat stood, so that when it got a shock it jumped to the other side of the cage. The conditioned reflex was developed by ringing a bell for 2 seconds before applying the shock. By repeating the combination of the sound of the bell and the electric shock Gellhorn set up a conditioned reflex, so that the rat would jump from one side of the cage to the other when the bell was rung and no shock was applied. Having developed this conditioned reflex, he reinforced it for two or three days by applying both bell and shock, and then applied the conditioned stimulus alone, 10 times daily. After 4 or 5 days the rat no longer responded to the bell because, due to lack of reinforcement, the reflex faded. If now he subjected the rat to shock "therapy," either by causing convulsions electrically, or by injecting leptazol, or by injecting insulin and producing coma, then when this experience was over, the conditioned reflex was restored to a greater or less extent and for a longer or shorter time. Electrical convulsions were least effective in restoring the conditioned reflex, being inactive in some rats and only temporarily active in others. Leptazol was intermediate in efficiency, while best of all was insulin coma. Two or three periods of insulin coma, at suitable intervals, often fully restored the conditioned reflex, so that the rat responded every time the bell was rung and continued to do so for as long as 11 or 12 weeks. One other observation of importance was made. Some resistant rats in which insulin coma had little and transitory effect, so that the conditioned reflex was not restored, had injections of thyroxine. The conditioned reflex was then restored even by electrical convulsions, though these were quite ineffective before the thyroxine was given. Gellhorn believes that the action of thyroxine was central because the amount used did not potentiate any peripheral sympathetic effects.

The interest of these results for the clinician is obvious enough, for much good social behaviour depends on reflexes which are induced or conditioned. Gellhorn's work seems to be a fairly accurate experimental reproduction of what is probably happening in shock therapy, and throws quite new light upon it.

EPISIOTOMY

Laceration of the perineum is probably the commonest lesion of childbirth. This has been recognized from the earliest days, and Hippocrates advised the use of oil and hot douches to soften the parts and thus prevent rupture of the perineal tissues. The importance of preserving the perineum intact, if possible, is rightly emphasized in the teaching of medical students and pupil midwives. In a recent article in this *Journal*[1] J. D. S. Flew suggests, however, that the attempt to preserve an intact perineum may be made at too great a cost. Not only may the second stage of labour be prolonged, with harm to the mother and child, but overstretching of the vaginal walls and their supports may lead to prolapse, particularly to cystocele. The vaginal walls may also be lacerated, even though the perineum remains intact. Such lacerations may go unrecognized and thus be left unrepaired, with consequent risk of sepsis. Because of these dangers Flew recommends early episiotomy in all cases in which delay in the second stage of labour is caused by the resistance of the perineal tissues.

In spite of the best obstetrical skill, spontaneous laceration of the perineum is inevitable in many cases. The question then arises whether it is better to allow the perineum to tear or to anticipate this by a deliberate incision of the tissues. The difference between a minor laceration and an episiotomy is probably slight. It is rarely easy, however, to judge where a spontaneous laceration will end, and it may extend into the rectum. Such lacerations are often ragged and accompanied by much bruising of the tissues, which makes their repair difficult. Flew therefore advocates early episiotomy, and his view has been supported in a letter to these columns from T. N. A. Jeffcoate,[2] who, while he does not agree that episiotomy will prevent prolapse of the uterus in all cases, believes it to be particularly valuable in the prevention of cystocele. There are many indications for episiotomy. Flew has remarked on its value in cases of foetal distress, as when the head is on the perineum. He also quotes Berlind,[3] who advocated episiotomy in cases of premature delivery in order to prevent cerebral haemorrhage. Forceps cases and breech delivery, especially in primigravidae, are much eased by episiotomy. (Burns and Marshall[4] recommend the injection of 50 c.cm. of 0.5% procaine into the perineum as a preliminary to episiotomy in breech delivery in a primigravida.) Episiotomy is indicated in spontaneous delivery of an occipito-posterior position face to pubes in face presentation, in cases in which the pubic arch is narrow, and in any patient who has previously had a colpoperineorrhaphy or a severe laceration. Episiotomy may also prove of value when it is desirable to hasten delivery—for example, in cardiac or pulmonary disease which calls for a shortening of the second stage.

When should episiotomy be performed? Flew recommends that it should be done when bulging of the perineum is apparent, and points out that an episiotomy performed too early is preferable to one performed too late. Four possible sites for the incision have been described: lateral medio-lateral, median, and multiple small incisions around the vaginal orifice. Of these, most obstetricians prefer the medio-lateral, but Flew describes a J-shaped incision, beginning as a median incision and turning to one of other side to avoid the rectum. In any case it should begin at the midline at the fourchette. Bilateral episiotomy is mentioned only to be condemned, since the blood-supply to the perineum is cut and sloughing may result. The medio-lateral episiotomy can always be extended to give as much space for delivery as is required. After episiotomy the perineum and vaginal walls should be repaired in layers, and this should be done with care. If the incision is medio-lateral it must be remembered that it has been made obliquely and thus must be repaired obliquely Local analgesia should be induced except in cases of operative delivery under general anaesthesia. In the latte it is reasonable, provided the patient's general condition is satisfactory, to continue light anaesthesia while th necessary sutures are inserted into the perineum. In th great majority of cases the results of episiotomy are highl satisfactory, and the incision usually heals by the end o a week. The most usual cause of failure of healing i sepsis, and, when the perineal wound breaks down becaus of this, early secondary repair, as soon as the raw su faces are clean and granulating, should be performed—relatively simple procedure that may save the patien months of discomfort and often permanent disability.

PERITENDINITIS, OR FOOT-SLOGGER'S NODULE

BY

H. DAINTREE JOHNSON, F.R.C.S.

Major, R.A.M.C.; Surgical Specialist, Parachute Field Ambulance

This condition is uncommon in peacetime and, to the best of my knowledge, has not hitherto been described, though it must be familiar to the medical officers of all hard-marching units. I have seen many cases in an airborne division in which the men are trained to march up to 50 miles in 24 hours. The lesion presents as a painful swelling over a tendon, and always corresponds to a point of pressure such as a fold in the leather of a boot. It occurs particularly on the tendo Achillis, the tendon of the tibialis anticus, and the flexor tendon of the hallux. Pain comes on during a march and causes alteration of gait and limping or clawing of the toes in an effort to relieve pressure on the tender area. There is characteristically no pain at rest, and this helps to distinguish the lesion from an infective one.

On examination of a recent case there is found to be some firm localized swelling over and round the tendon. The swelling is tender to firm pressure with the fingers, but not nearly so tender as an infective lesion. However, continued trauma by the hard boot-fold is very painful. If the condition is not treated and the offending boot continues to be worn, a hard thickening forms and there is crepitation on movement. Gradually it becomes a well-circumscribed elevated nodule, or often two nodules with a groove between, each about 3/4 in. wide and 1/4 to 1/2 in. thick. The nodule is closely adherent to the skin, but can be lifted off the tendon, and does not appear to be connected with the tendon sheath, when present. On account of the crepitus the early cases are often sent to the specialist with a diagnosis of "tenosynovitis." It might be noted, therefore, that crepitation is most common in the tendo Achillis variety in which there is no tendon sheath. Tendinitis is also becoming a popular diagnosis of unelucidated pathology, but there is no evidence for it here.

When there is a groove between two nodules it is in the groove that tenderness is most pronounced. The groove corresponds to the causative crease or lace. This I have seen most commonly over the tibialis anticus tendon, where it is produced by that cross-piece of the lace which is most nearly opposite to the ankle-joint and is most likely to cut in on dorsiflexion of the foot.

Aetiology

It is usually found either that the sufferer is a new recruit or that he has a new pair of boots or an old pair in which the stiffness of the leather has suddenly given way, forming a new crease. I have never seen the condition occur with really old well-softened boots. Boots which are too large are as likely to cause the condition as those which are tight. In fact, the hallux type occurs typically with boots that are too long and which form a deep crease just behind the toe-cap.

The commonest site for peritendinitis is over the Achilles tendon, as it is here that a fold always forms if the boots are laced to the leg above the ankle-joint. The crease projects forwards as shown in Fig. 1. Tightly strapped gaiters are an important factor in making this crease, and the lower strap of the gaiter should always be quite loose when the foot is plantar-flexed. It would seem that the lesion is caused not by friction on the skin, which produces a blister, nor by pressure, which makes a callosity, but by repeated indentation.

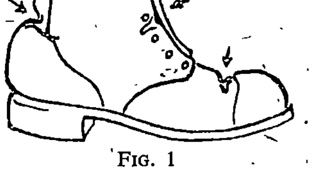

FIG. 1

Since it is only seen in its typical form over a tendon, it would appear to represent the special response of paratenon tissue to this type of trauma.

Pathology

The established nodule is seen, on section, to be a mass of simple avascular fibrous tissue with a very few inflammatory cells. No abnormality of tendon or tendon sheath could be found in the specimens available, but the paratenon fatty tissue was largely obliterated. The skin showed only a little keratinization—within normal limits for the areas concerned. The specimens were from chronic cases. In recent cases there are, clinically, hyperaemia and slight oedema.

Treatment

Removal of the cause is all that is necessary to effect a cure in most cases. If the trauma is discontinued the lumps get smaller and the redness and tenderness rapidly disappear. But there is a marked tendency to relapse, and recurrence is certain if the patient returns to the same boots without dealing adequately with their faults. The boots must be eliminated, softened, or stiffened, according to the indications.

If new boots are supplied the soldier should be warned against softening the back, which should remain stiff and creaseless. He should be told to leave the lower strap of his gaiter quite loose. He should avoid lacing the boots tightly above the ankle, in order that a fold shall not form at the back. If a crease has formed at the back of the boot, softening seldom helps, and it is best stiffened with a small tin splint such as that illustrated (Fig. 2). This functions by curving the leather from side to side and so making it more rigid. The splint may be quite thin, and is easily made with an old pair of scissors out of a cocoa tin. The edges are toothed and turned in as shown, so that the appliance will clip on to the back of an Army boot.

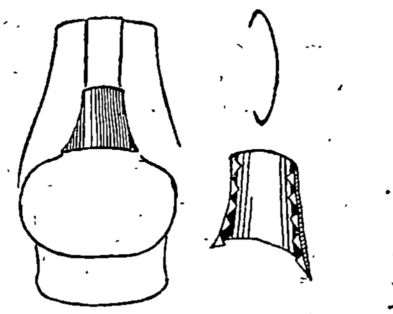

FIG. 2

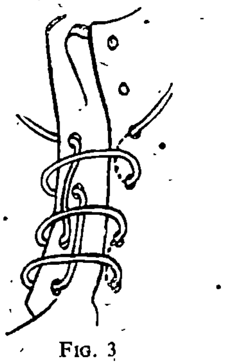

FIG. 3

If a crease has formed just behind the toe-cap and caused peritendinitis over the base of the hallux it is probable that the boots are too long. A crease is also liable to form here when the soles are becoming too pliable and the boots need resoling. Boot trees, or packing the boots with paper at night, help to prevent this crease. Once formed it can be treated by splinting with a patch of leather, or it may be made innocuous by thorough softening with oil. (Dubbin does not soften leather.) The best method, however, is to raise the crease off the foot by sticking a piece of chiropodist's felt about 3/16 in. thick inside the boot. This will often cause the leather to fold outwards instead of inwards.

When the lesion is over the tibialis anticus tendon and is caused by the lace, the soldier should be taught to lace his boots as in Fig. 3, so that the laces do not cross the tendon beneath the leather, but only in front of it. Soft laces should be substituted for leather ones. Lastly, a strip of chiropodist's adhesive felt should be stuck inside the tongue of both boots.

Patients should be excused boots altogether until the area is no longer red and tender, though marching may be allowed in any other footwear that does not cause pain. I am not convinced that any local treatment affects the rate at which the lesion settles, but various counter-irritants are sure to have supporters. Injection of novocain round the swelling is a good first-aid measure, and is invaluable if the symptoms come on during a long operational march, but it will not cure the condition. Injection *into* a developed nodule is impossible.

In a series of over 20 cases I have seen only one man who has been permanently unable to march in Army boots. He had strikingly prominent tibialis anticus tendons, and I could devise no method which gave him adequate protection short of leaving the boots completely unlaced. One other man was down-graded for this condition, as we could not get him up to the marching standards of the division. Both these men could march well in shoes, as can many others who are poor performers when their ankle-joints are splinted by boots.

I have on one occasion excised the nodules on a very chronic case, but it is difficult to get the scar out of harm's way, and the psychological effect of surgery was bad.

I am indebted to my A.D.M.S., Col. M. MacEwan, D.S.O., O.B.E., D.F.C., for permission to publish this article.

INDUSTRIAL MEDICINE

A COLLEGE OF PHYSICIANS REPORT

Nearly three years ago the Royal College of Physicians of London set up a Social and Preventive Medicine Committee with a wide reference. The committee began its work by considering social medicine from within the hospital, on which it published its first interim report. Then it began the task of investigating social medicine outside the hospital, taking, as the first and most obvious field, the role of medicine in industry. It is with this subject that a second interim report deals.

The demand is made by the committee which has drawn up the report that the industrial health service should be planned in a bold manner, without much regard for traditional arrangements. It should be part of the projected National Health Service, with the ultimate responsibility vested in the Minister of Health. In the regional organization of the service the universities should play an important part, and here the recent endowment by the Nuffield Foundation of three university departments in industrial medicine provides an excellent example.

The Present Unequal Provision

Medical services apply at present only to a small proportion of industrial workers at their place of work. Nearly all the whole-time medical officers are attached to organizations employing over 1,000 workers; yet—at all events before the war—more than half the workpeople in this country were employed in factories in which fewer than 250 operatives were working, and in only a few such industrial establishments was there medical supervision even by part-time officers.

A quarter of a million establishments are covered by the Factories Act, 1937. To-day there are nearly 200 whole-time and 700 part-time works doctors. Some of the part-time works doctors are also examining surgeons, of whom there are over 1,700, but most of these do not carry out personal medical treatment. The medical side of the factory inspectorate has developed slowly, and there are now only about sixteen medical inspectors, who act more or less as a small body of consultants in addition to their routine duties.

Beyond the territory of the ordinary provisions of the Factory Acts there are, for example, the workers employed in offices and business establishments, in hotels and catering organizations, in transport services, in temporary constructional works, and in a considerable section of agriculture, and all these occupations have their health risks. The report holds that the immediate requirement is for a comprehensive health service which will cover these "outside" industries and will apply to small concerns as well as large.

The family doctor has a vital part to play in such a service as a part-time industrial officer, and, says the committee, he must be trained for this function. There must also be a national service of medical officers of consultant rank who have specialized in the problems of occupational disease.

A National Industrial Health Service

The industrial health service will be concerned primarily with the working environment. Its duty will be to see that the individual is fitted into his setting; for this purpose a knowledge of his physical and mental capacity will be necessary. This will pertain not only to the people entering industry for the first time but to workers passing on from one occupation to another on account of recent or persistent illness. Another function will be the prevention of occupational disease, a task calling for the help of clinical consultants and scientific research workers. The prevention of injuries, the co-ordination of health and safety measures, the organization of a service of general health supervision and emergency treatment of illness and accident, and aid in rehabilitation, the final stages of which must be carried out at the place of employment, are all tasks which will fall to the service. To these must be added the resettlement of permanently handicapped workers, whose case calls for the same continuity of medical care and linking together of services as does the rehabilitation of those who return to full earning capacity.

The report also suggests joint management–labour committees to arrange for the health education of the workers, the dissemination of information, and the collection of problems requiring study. The service would provide instruction in and technical study of lighting, heating, ventilation, welfare organization, and the nutritional aspects of works canteens. Finally, the work done in the industrial field would need to be integrated with the other medical services of the area, provided by general practitioners, hospitals, and specialist units.

Finance and Appointments

The committee brushes aside any objection that industry cannot afford a health service; it cannot afford to be without one. The most obvious way of financing the service would be for industry to pay for it, but the workers would be suspicious of medical officers in the pay of the management; moreover, elaborate pooling arrangements would be necessary for small undertakings. If a close relation between the national and the industrial health service is maintained, payment might be part of the general health budget. Alternatively, the cost of the service might be met by a levy on output or profits. Some combination of two or more methods might be considered, and the possibility of sharing the costs between industry and central funds might offer a satisfactory solution.

One method of making appointments to the service would be through the Local Health Services Councils as outlined in the White Paper, provided industrial representatives were included among its members. The ultimate aim in training is a much better grounding in industrial medicine for medical students intending to take up general practice; meanwhile, with a view to part-time services, short courses should be arranged, lasting about six weeks, combined with refresher courses from time to time. For the man who wishes to make industrial health his career, it is considered that a special well-designed course lasting one year should be undertaken, to be preceded by at least two years' postgraduate experience in medicine, of which not less than one year should have been spent in general practice.

A diploma in industrial health would help to establish a minimum standard of training and qualification, but this must await a study of the general question of postgraduate diplomas. For consultants and specialists in industrial medicine there would be required a period of three years of specialist work including a junior post in a university department, some experience in research, and possibly some experience abroad. The committee holds that research in industrial health should be given every administrative encouragement. The Industrial Health Research Board must continue, and there should be departments of industrial health in university teaching centres, while in each local administrative area a division for field investigation, working in close touch with the Industrial Health Research Board and the local factories department on the one hand and the university and local industries on the other, would be desirable.

In the Government White Paper on a National Health Service industrial medicine is treated only in one short paragraph and to a rather greater extent in one of the appendices, but only in the form of a statement of the present position. The R.C.P. Committee has filled a very obvious gap.

Reports of Societies

DEVELOPMENT OF HEALTH IN ADOLESCENTS

The meeting of the Section of Medicine of the Royal Society of Medicine on Jan. 23, with Dr. GEOFFREY EVANS in the chair, was devoted to the subject of the physical training of adolescents. A film was shown of the methods and results of the physical development centres for substandard Army recruits.

Brig. FRANK HOWITT said it was curious that the medical profession, with its tendency to specialize and departmentalize in every direction, had paid so little attention to the problems of adolescence. Before the war anyone who came forward with a demand for attention to national physical fitness incurred the charge that he was preaching militarism. The adolescent had no political foster-parent, but lay in the no-man's-land between the Ministries of Health and of Education. Thus there developed a tendency on the part of the masses to spend their leisure in watching contests rather than taking part in them.

It was the good fortune of Army physical medicine, which looked upon itself as part of general medicine, to be entrusted with the selection of cases for the Army physical development centres, their medical control at the centres, and their final assessment. At the centres both preventive and corrective treatment were directed to meet the specific demands of the Army. The aim was to produce by exercises and supervision a correct habit of posture, locomotion, and performance of physical tasks, while the necessary mental stimulus was provided by games and competitions. Individual treatment was given where required, and the masseur, the chiropodist, and the dentist each had his function. Routine medical examinations were held at the beginning, middle, and end of the course. A centre had been established for substandard recruits of the A.T.S., and although no great muscular development was aimed at in their case it was remarkable what improvement was effected in stance, appearance, and general health.

One of the chief difficulties in the future under any scheme for the training of youth would be the question of compulsion. In peacetime persuasion would be required, and persuasion was dependent on motive. The appeal to youth must be pragmatic and practical, even selfish, based on self-advancement and increase of personal prestige. Finally, in teaching hospitals there should be a preventive as well as a curative department, to which should be referred all substandard conditions, fatigue states, anaemias, recurrent infections, and early structural deviations—conditions which were sometimes foolishly referred to as minor maladies.

Army Experience and Testimony

Major-Gen. Sir GUY DE C. GLOVER said that his Army experience of physical training exercises went back to the last war, when he was for a short time with a division made up of "bantams." Not only were disabilities improved as a result of physical exercises but there was a change in the entire mental attitude of the man. The War Office was so impressed with this that in due course the first physical training centre was started at Aldershot, and, at one time, of 2,300 men who had been through the course there, 2,000 had been upgraded and had become useful in the Army. During the present war several physical development centres were started. It was found preferable to make them actual Army units under a commandant, because then the men felt that they were really soldiers and not convalescents. There were, of course, also a large number of convalescent depots where similar exercises were carried out, but these were for men who had been wounded or sick, whereas the physical development centres were of a preventive character, and men went there immediately on joining the Army. Up to the present time 27,000 men had been put through the courses, and 20,000 had emerged as thoroughly efficient soldiers, benefiting not only in physique but in intelligence, and acquiring pride in themselves. In fully 50% of the cases there had been a gain in intelligence as well as in physical qualities, and the more intelligent the men to begin with the more strikingly the intelligence developed. "These centres," said Sir Guy Glover in conclusion, "are invaluable to the Army."

Effect of Competitive Exercise

Sir ADOLPHE ABRAHAMS spoke on the influence of competitive exercise. The familiar accompaniments of severe physical effort, he said, provided a prima facie case for its condemnation. The appearance of distress and suffering, the occurrence of exhaustion and collapse, all contributed to the conviction that injury to the vital structures could hardly be avoided. Admittedly the stress upon the circulation was severe. Nearly 40 years ago, in a letter to the public press, half a dozen eminent members of the profession condemned cross-country running for boys. Their opinion was warmly challenged, and the Association of School Medical Officers, after due investigation, came to the conclusion that there was no ground for alarm. At a later date Dr. L. R. Lempriere, medical officer at Haileybury, brought forward the collected experiences of himself and other school medical officers, covering 16,000 boys, showing that in 30 years, excluding a few genuine accidents, only one death on the football field could be recorded, and even in this there was no evidence of a lesion which might be attributed to exertion.

It was confidently maintained by leading cardiologists that the reserve of a healthy heart was so considerable that no effort, however great, could produce any harmful effect. When the call was excessive it was other, less important, factors which failed. The heart was not, as was frequently implied, an isolated organ working by itself. It represented the central fortress of the organism, the defending position and outposts being provided by the nervous system and its servants. When alleged cases of heart strain were examined it was found that some were examples of long-standing lesions, which, having given rise to no symptoms, had been unrecognized until the breakdown; some were merely instances of innocent natural peculiarities mistaken for pathological conditions; and some—the majority—were the symptoms of nervous instability, with special relation to the vasomotor system, particularly in respect to the lability of puberty, when so many demands upon energy were simultaneously made through the exigencies of growth, the integration of the endocrines, the mental pressure and anxiety over examinations, and the like.

The idea of adolescent strain to some conveyed the impression of a limited store of energy, specially inherent in the heart, which was provided for the whole of life for prudent expenditure and might be prematurely exhausted by spendthrift living. The failure of schoolboy prodigies to develop in accordance with their early promise was regarded as evidence in support of this idea, especially as it provided a convenient excuse for prophetical failures; while the "burnt-out athlete" was left with the reputation of martyrdom. The true explanation rested on the fallacy of regarding growth and development as subject to a universal law instead of as an individual problem. Often the "curve" of athleticism rose rapidly to its peak, and then, after remaining horizontal for a variable period, progressively declined.

Of the girl athlete Sir Adolphe Abrahams said that, with appropriate modifications, the same physiological and pathological considerations would apply. He refrained from any detailed consideration for three reasons: he had had very little personal experience; the cult of competitive exercise was, speaking generally, less applicable for girls; and the physical well-being of schoolgirls had for some time been organized on a scale that might well be followed in the case of boys. It might smack of Victorian narrow-mindedness to display solicitude for the preservation of those qualities which were traditionally associated with femininity, for the avoidance of the danger of over-development of certain masculine traits by indulgence in severe competition, not to mention the disadvantage of diverting energy from channels for which it was particularly required in preparation for the burdens of womanhood and possible motherhood. Special investigations had decided that there was no evidence to support the fear that muscular development prejudiced normal pregnancy and parturition, although some gynaecologists remained unconvinced. The nervous side, however, deserved paramount consideration. Highly competitive efforts such as first-class lawn-tennis tournaments, in which the leading players attained a wide publicity, had the disadvantage not only of creating a wrong sense of values but of producing an anxiety state and general ill-health which were not so much the direct consequence of exertion as of the concomitant circumstances.

The Public School System

Dr. G. E. **FRIEND** (medical officer of Christ's Hospital) said that the development of health in adolescence depended upon four main factors: (1) the provision of an adequate and well-balanced diet; (2) adequate sleep and rest; (3) properly balanced physical development, which in turn depended on a proper ratio between games, physical training, and education; and (4) avoidance of over-fatigue. The chief function of the school medical officer was preventive rather than curative. He agreed that the average youth required a motive to make the necessary effort for his physical development. He had himself conceived the idea that the Greek ideal of perfect physical development and fitness was the right motive to inculcate, provided it was suggested to him as development purely for its own sake. Boys hated to be thought altruists. The J.T.C. and A.T.C. and other semi-military pursuits in school at the present time were unpopular with the majority of the boys, not because the boy was not patriotic but because the duties of the course were compulsory and took time from games. Competitive games and sports were character-forming. Military activities would be much better if they could be amalgamated with something on the lines of the Boy Scouts—that is to say, there should be less marching and forming fours, and more physical training and week-end camping, also more first-aid and more field work such as engineering and signalling.

In some further discussion Sir **MORTON SMART** said he was pleased that at last there had been some co-ordinated effort for the training of the adolescent. In the Army and Air Force there were unquestionably great opportunities for this, which were not likely to continue when peace came and the majority of the men in the Services were released. If a start could be made at school and training be given in the pre-adolescent stage the whole matter would be more or less simplified. Dr. **ROBERT SUTHERLAND** spoke to the same effect. One of the most useful contributions which could be made would be to discover appropriate preventive measures to be applied to the pre-adolescent, so often the helpless victim of circumstances.

EFFECT OF DIET ON INDUSTRIAL POISONING

A number of foodstuffs have from time to time been supposed to ameliorate the effect of industrial poisoning. The principal favourite among these is milk. When, however, the scientific basis for the administration of specific foods as a protection against poisoning is considered, very little proven information can be found. At a meeting of the Nutrition Panel, Food Group, of the Society of Chemical Industry on January 16, Dr. H. Taylor of I.C.I. suggested that the best means to avoid industrial poisoning was to take steps to prevent work-people from being poisoned at all. This advice was confirmed by Dr. R. E. Lane, Dr. Merewether, and other speakers at the meeting. Dr. **TAYLOR**, who opened the discussion, mentioned a number of foodstuffs that were thought to be protective. The first, of course, was milk, but whether its alleged protective action lay in the calcium it contained, the methionine, or the riboflavin, could not be stated. Vitamin C was also a nutrient popularly supposed to protect the blood-forming organs against injury by toxic solvents; and German work, published, it need hardly be said, before the war, recommended a daily diet including 18 oranges and 18 lemons as suitable for workers exposed to such risks. Dr. **LANE** discussed some of the aspects of lead poisoning, and he emphasized that absorption through the lungs was probably ten times as dangerous as absorption by any other route. For example, lead passing into the alimentary tract might not be absorbed at all, and if it were absorbed it might be excreted in the bile before harm had been done. Even after absorption a portion of the lead might be re-excreted comparatively harmlessly and another portion might be tied up in the bones. In attempting to prevent lead poisoning a number of dietary factors have been suggested; one of these is pectin. Milk is advised sometimes merely to occupy the gastric juices, sometimes for its high calcium content. At other times low-calcium diets are recommended in an attempt to prevent the storage of lead in the bones. Copious amounts of water are also recommended to protect the kidney, and the diet should be designed to prevent constipation, and hence to assist the excretion of lead from the alimentary tract. Although Dr. Lane mentioned all these different dietary possibilities, the suggestion which he made, and in which one could gather he himself was best convinced, was that in order to prevent lead poisoning a good prescription was to pay high wages, employ intelligent work-people, provide them with a good supply of drink—whether it be tea or water—and, after all this, perhaps provide them with milk.

The increased resistance to industrial poisoning of people in this war as compared with those of the last was mentioned by a number of speakers. This could be attributed perhaps to better living conditions, perhaps to better diet, or perhaps to the fact that in this war fewer young people were employed in hazardous work than had been the case in the last Prof. **HIMSWORTH** mentioned the different susceptibility to liver damage of different strains of rats, and wondered whether this might, in part, also explain the different susceptibilities of work-people. He also pointed out the general similarity of the symptoms due to poisoning—for example, by selenium—and those due to certain types of nutritional deficiency. I was an attractive and plausible hypothesis that poisons interfered with one or other parts of an enzyme system, and perhaps the hope for future development of dietary treatment to prevent poisoning lay in discovering which these parts of the system were and providing high amounts of the substances involved in food. Mr. A. L. **BACHARACH**, from the chair, referred to work on selenium poisoning, in which, by means of labelled molecules, it had been shown that selenium took the place of sulphur in the methionine molecule, and hence caused what might almost be described as a conditioned protein deficiency.

From all this discussion and more it was made plain tha much could be hoped for in the future from a scientific study of the nutritional prevention of industrial poisoning. A present, however, many of the methods used and, in particular the wholesale prescription of milk, could not be justified on scientific grounds. All speakers, however, were agreed that to obtain the best chance of protection, work-people exposed to toxic substances should be given the best balanced diet possible

Nova et Vetera

MEDICAL EPONYMS

The medical student at the outset of his career is confronted by a number of diseases, symptoms, and treatments to which are attached the names of hitherto unfamiliar persons. Recently there has been a plea for the dropping of such labels, but many would regret this departure from tradition, though when four names are attached to the signs of exophthalmos one may well feel it is time to call a halt. It was a happy idea of Mr. **HAMILTON BAILEY** and Mr. W. J. **BISHOP**, in their *Notable Names in Medicine and Surgery* (H. K. Lewis; 15s.), to give a brief account of 83 persons, including two women, whose names are associated with some discovery. It is also an added advantage to have a portrait of each with an illustration or diagram elucidating their contribution to the subject. The authors lay no claim to completeness, but others besides students will glean many interesting facts from these pages Thus we are informed that Meckel's diverticulum was described by the grandson of the discoverer of Meckel's ganglion. Three general conclusions will be drawn by the reader: first, tha a man's name may be attached to quite an insignificant par of his general contribution to medicine—thus Heberden thought very little of the nodes by which he is generally remembered rather than by his rationalizing of pharmacology; secondly the enormous sterile interval between Galen and the 16th century; and, thirdly, the international character of medicine which recent political events have done so much to endanger

Correspondence

Neglected Children

Sir,—Your leading article on neglected children (Jan. 27, p. 124) is most gratifying. For over a year I have been trying to arouse interest in the problem of neglected children. Since I brought this problem before the local branch of the Council of Social Service they have been most helpful, and some progress has been made in the face of fearful difficulties. We have recently had letters published in most newspapers, although one or two—typical, perhaps, of the general apathy and official indifference—have not published our communications. It may be that they thought our descriptions of local cases of neglect and squalor too loathsome to publish. One M.P., indeed, asked us not to print some of the details because of the damage which might result to our national prestige!

In the two Doncaster courts since Dec. 2 last I have personally given evidence in 14 cases of gross neglect involving 68 children. There are many more cases in this district (and we do not think that ours is an unusually bad one) which ought to be brought to light, but magistrates and the N.S.P.C.C. are up against a tremendous difficulty. There is practically nowhere to put these children while their parents undergo any sentence for their gross neglect. Furthermore—and this is a great deal more important—when the parents are released the children have to be returned to the appalling homes from which they have been temporarily rescued, there to be "looked after" by now embittered parents. The children's homes are all full and have waiting-lists. One home has lost 2,000 beds to a Government Department. This lack of provision for neglected children is, apart from the humanitarian aspect, a great waste of the nation's most precious asset—healthy and fit children.

I cannot take up space explaining why foster parents are not the answer to this problem. Local authorities are, naturally, very prone to say they are. If they were, much expense and difficulty would be easily overcome. What is needed, and very urgently, is the provision of many more beds in well-run children's homes. There are many empty premises in the country to-day under the control of different Government Departments; there are many civil defence workers not required any longer for C.D. duties. If only the need could be realized the staffs and the homes could be provided. The Ministry of Health, the Board of Education, and the Home Office are all involved, and are all apt to blame one another.

There is shortly to be held a Parliamentary inquiry into the management of children's homes. If readers could persuade the Ministries concerned to hear evidence on the dire need for more homes they would have done a great service to the country. It is probably true to say that many thousands of children are at present being reared in conditions worse than in an average stable. Yes, this is literally true if unpalatable. Help in bringing this fact to notice is urgently needed. I can willingly give anybody asking for them exact reports of scores of almost unbelievably shocking cases.

Dr. A. E. Martin, according to your leader, stresses the need for adequate supervision of these cases by the local authorities. I wish I had space to emphasize the value of this observation. I must apologize for having taken up so much print already, but this problem concerns one of the most serious blemishes on our social services, and there is no room for any complacency. We are all busy, but not too busy to help in this matter.—I am, etc.,

Doncaster. Robt. W. L. Ward.

Nature of Injectable Liver Extracts

Sir,—The article by Messrs. W. B. Emery and W. J. Hurran on injectable liver extracts (Jan. 20, p. 75) is both interesting and timely. It is good that attention should be drawn to the advantages which would result from the establishment of an official unit of activity. The authors have mentioned some of these, but have omitted the very important fact that it would bring to an end the marketing of liver extracts possessing little or no potency. How frequently this occurs one can only guess, but from my own experience I should say that it is certainly not rare. Since I have seen several severe remissions of pernicious anaemia due to the use of such extracts, I think it quite likely that some deaths have resulted from the same cause. Great accuracy cannot yet be claimed for any method of assessing the potency of liver extracts, but even an approximate estimate is better than none at all.

If, as I earnestly hope, some official action is taken in this matter, the system of units to be adopted will have to be decided upon. It will be unfortunate, I think, if different countries adopt different standards. The U.S. have defined a unit of potency; Canada has followed suit with a slightly different definition; and now Emery and Hurran have proposed a third. Since the accuracy of any of the methods is probably not great, it would seem essential to use one system if the results are to be comparable.—I am, etc.,

University of Aberdeen. Harold W. Fullerton.

Management of Colitis

Sir,—In the *Journal* of Aug. 26 (p. 278) there appeared a review of my monograph, *The Modern Management of Colitis*, which contained some rather surprising statements. The reviewer apparently objected to our inclusion of cases of tuberculous colitis, amoebic colitis, and the colitis due to the venereal lymphogranuloma in a discussion of ulcerative colitis. This is most unusual, for are not all these conditions infections of the large intestine? He states that "about 250 cases of ulcerative colitis enter the Clinic each year." He has been considerably misinformed in this regard; for many years we have seen many more patients with ulcerative colitis than this annually, and in 1943 we saw 520 patients with ulcerative colitis of the Types 1, 2, and 3 alone. No attempt was made to completely cover the literature on ulcerative colitis, nor would I consider this indicated in a volume of this type. An attempt was made to select a few authors representing the various views concerning aetiology. I think the reviewer is correct in suggesting that there was little advance in the subject of ulcerative colitis between the early papers and the one by Dr. Logan published in 1919.—I am, etc.,

Mayo Clinic, Rochester, Minnesota. J. A. Bargen.

Nursing of Tuberculosis

Sir,—Your annotation (Oct. 28, p. 569) and the recent letters from distinguished authorities on tuberculosis show that, although there is no indifference to the problems connected with the nursing of tuberculosis, there is considerable divergence of opinion on the risks and dangers which that occupation involves. In fact, it would seem that the more that is written on the subject the greater the confusion becomes. This is not surprising in view of the paucity of accurate information on the fate of the primary lesion in young adults.

There is no doubt that tuberculosis is an infectious disease; nor will it be disputed that primary lesions are discovered in the frequently examined nurses during their course of training, but there is no proof as yet that as a profession they are more vulnerable than other selected classes of the population of the same age group. Neither is it certain that those nurses who develop active tuberculosis do so because they have been nursing tuberculous patients.

From the evidence of our village settlements for the tuberculous, where so far children brought up in tuberculous households have not developed active tuberculosis, we may assume that environment, mode of life, and medical supervision are the important factors that decide the future of the primary lesion. Would it not, therefore, be wiser to concentrate on the improvement of these factors in our hospitals and sanatoria rather than argue on the risks of infection?

With further development of the valuable work being done under the Prophit Bequest, we may, five or six years hence, be able to lay down with some degree of certainty the conditions of service in the nursing of tuberculosis. Until then let us see that no criticism can be made regarding the provisions for the general welfare, education, and medical supervision of our nurses, irrespective of the type of institution in which they may be working. By such action we shall do more to dispel the fear of infection and fill the depleted ranks of the profession than by advertising present inconsistencies of policy due to our incomplete knowledge of the dangers of nursing tuberculosis.—I am, etc.,

Public Health Department, County Hall, S.E.1. FREDERICK HEAF.

SIR,—In reply to the criticism of Drs. P. W. Edwards and A. Clark Penman (Jan. 20, p. 95) of my letter on tuberculous infection in nurses I should like briefly to make the following points:

I quoted the figures of Daniels (the numerical misprint was corrected in one of your subsequent issues) relating to tuberculous infection of nurses in general hospitals because the report of the Tuberculosis Association and Joint Tuberculosis Council was based on the impression—for there are no statistics in the matter—that tuberculous infection in sanatorium nurses was no higher than that in general hospital nurses. This is, to say the least, a negative attitude, and when it is proved by Daniels that Mantoux-negative nurses in general hospitals have a high tuberculosis morbidity the case for employing such nurses in a tuberculous environment falls to the ground.

There are ample further statistics available from America and Scandinavia on the subject supporting my contention, but I need quote only those of Hansen (1943); in a paper read before a meeting of the T.A., showing that 27 cases of tuberculous illness occurred among 625 cases of Mantoux-positive nurses, whereas 96 cases occurred among 280 Mantoux-negative at the Municipal Hospital, Oslo. No death occurred in the positive group, while 11 deaths occurred in the negative group of half its size; which does not support the view of Drs. Edwards and Penman on the benign nature of primary tuberculous infection in young nurses. The truth, clearly indicated in the last paragraph of their letter, is that the laudable desire to keep beds open has blinded the authors of this report to the statistical evidence. It is all the more unfortunate, therefore, that these views should receive favourable notice in your editorial, which, of course, has wide publicity and is likely to be considered authoritative.

The problem can, and probably should, be approached from another angle—namely, by B.C.G. inoculation of Mantoux-negative nurses. I believe that hundreds of thousands of persons have now been inoculated without a single case of progressive tuberculosis developing—the often-quoted Lübeck disaster of 20 years ago being due to mixing of cultures. In this connexion it is interesting to note that after hearing the paper by Hansen (already quoted) the T.A. were so impressed by the possibilities of B.C.G. vaccination that they passed the following resolution: "That the T.A. Council be instructed to approach the councils of the National Association for the Prevention of Tuberculosis and the Joint Tuberculosis Council with a view to a joint request to the Minister of Health to make B.C.G. available for trial in this country." It would be interesting to know what further has occurred as a result of this resolution.—I am, etc.,

Kinmel Hall Hospital, Abergele. W. E. SNELL.

SIR,—It should surely be possible to collect reliable figures as to the incidence of tuberculosis among nurses in general hospitals and in sanatoria. Any one of the big counties would have comparable institutions in which a statistically significant inquiry could be undertaken. All the evidence at present available points to a very considerable risk of infection, and most nurses certainly believe that there is great danger in this work. We know that Mantoux-positive reactors are less likely to acquire the disease, and it would be ideal if negative reactors could be excluded from tuberculosis nursing. I cannot, however, agree with Drs. Edwards and Penman (Jan. 20, p. 95) that "a sanatorium is as good a place as any other in which to acquire tuberculin sensitivity." Intermittent exposure in a general hospital ward, cinema, or public transport vehicle must on theoretical grounds offer a better chance of building up an immunity than does massive exposure.

At the present time I know of no compensation scheme for nurses—or doctors for that matter—who contract tuberculosis in the course of their work, and thus lose their careers and perhaps even their lives. If the risk is as small as some would have us believe, then adequate compensation would not be very expensive, but if the risk is genuinely great, then financial security should be offered at any cost. Routine *x*-ray and tuberculin control should mean that only healthy subjects are employed in the first instance, and that if they develop tuberculosis it has been acquired during the period of their service. The staff requirements of hospitals and sanatoria are well known, and I would not wish to see them aggravated in any way, but in fairness to the nurses the facts should be honestly faced.—I am, etc.,

London, W.1. ALEC WINGFIELD.

SIR,—The risks which face any girl who takes up the nursing of tuberculous patients are serious enough even under the best possible conditions and with the greatest possible care. Are we sure that all safeguards which can be used to protect nurses from contracting tuberculosis *are* being employed?

I have recently been consulted by two probationers from two separate sanatoria. One told me she had arrived at her hospital as a raw recruit at midday and by teatime was on duty in a tuberculosis ward without any instruction whatsoever in methods of protecting herself against infection. When I saw her she had an acute tuberculous bronchopneumonia. The other probationer told pretty much the same story—of emptying sputum mugs, etc., without any preliminary advice, not even to wash the hands after this necessary but odious duty.

These girls were not trained nurses who could be expected to think for themselves, but girls completely ignorant of such things as asepsis and antisepsis. Each was employed by a local authority in different parts of the country. If their stories are true—and I have no reason to doubt them—do they not call for drastic revision in the ideas of some medical superintendents? We cannot expect more girls to come forward as candidates for this hazardous branch of nursing until they and their parents are assured that proper safeguards will be taken against infection.—I am, etc.,

Leicester. T. F. BOSTOCK.

Necessities for Very Sick People

SIR,—There is a crying need for some body of experts who could, *without* delay, authorize and obtain necessities for very ill people when such necessities were properly vouched for by the medical man or men in attendance. At present there is none. Let me give you an example.

I have a patient suffering from carcinoma of the stomach with peritoneal metastases. Alcohol in some form, preferably whisky, alone sustains the patient and gives sleep. Though both I and the doctor in attendance have certified the necessity no spirits of any kind can be obtained in the town where the patient lives, and the case is dependent on kind friends who, out of their own small supply, give a small quantity at irregular intervals.

The patient suffers continual abdominal pain, which is relieved by a rubber hot-water bottle on the abdomen. The one rubber bottle in the house was worn out and leaked. I certified to the Ministry of Health the need for an authorization to get a new one via the firm which, having such bottles in stock, would supply it if allowed to do so. That was some 3 weeks ago, and by Jan. 22 the matter was still under consideration (or shelved, or pigeon-holed!), and I have had no further communication since. There is a certain callousness about these Government Departments which justifies the worst fears of those who oppose medicine becoming one of them.—I am, etc.,

London, W.1. VICTOR BONNEY.

The Etherington-Wilson Method

SIR,—I cannot let Mr. Thomas Moore's suggestion (Jan. 27, p. 129), that surgeons and anaesthetists who practise this method are careless and imprudent, pass unchallenged. Excluding the grosser errors due to ignorance and inexperience, the improper selection of cases for spinal analgesia is the decisive factor in producing fatalities. Babcock, in whose clinics spinal analgesia had, in 1938, been used upwards of 40,000 times, states: "If a writer reports fatalities, he also reports his personal incompetence."

I have used the Etherington-Wilson method for obtaining high blocks ever since its introduction, and lately his recent modification (*Proc. roy. Soc. Med.*, 1944, 37, No. 9, 545).

with great satisfaction in conjunction with no less eminent a surgeon than that brilliant technician, the late Mr. Cecil Joll. We had no immediate mortality attributable to spinal analgesia, nor did we ever encounter a case of respiratory paralysis due to involvement of the phrenics; this statement can be verified by our case records, which are available for inspection. Fatalities will be found to be associated with the abuse, not the use, of this simple and accurate method for obtaining a high spinal block.—I am, etc.,

Aylesbury. H. W. LOFTUS DALE.

Civilian Respirator as Anaesthetic Mask

SIR,—As one who, in common with Dr. J. Morland Smith (Dec. 23, p. 820), deplores the present-day desecration of Dr. Clausen's originally excellent harness, I was extremely interested to read Dr. F. S. Vaughan's account (Jan. 27, p. 131) of a civilian respirator converted for use as an anaesthetic face-piece. It would be interesting to know whether he finds the inevitable increase of dead space, occasioned by having the expiratory valve at a distance from the face-piece, any disadvantage. Also, if he uses it only for closed-circuit anaesthesia, and whether under these circumstances he finds there is a "build-up" of carbon dioxide in the extra piece of corrugated tubing.—I am, etc.,

MARGARET JOAD,
King George Hospital, Ilford. Resident Anaesthetist.

The Medical Film

SIR,—The Scientific Film Association welcomes the attention that was drawn in the leader of Jan. 20 (p. 87) to the present lack of suitable films for medical education. The association, while possibly not in agreement with all the criticisms therein, would point out that the correction of the deficiencies referred to is one of the main objectives of its work through its Medical Standing Committee.—We are, etc.,

W. MCADAM ECCLES,
Chairman
S. J. REYNOLDS,
Hon. Secretary,
Medical Standing Committee.

Scientific Film Association,
16, Princes Gate, S.W.7.

Aggressive Impulses in Progressive Society

SIR,—While fully endorsing Dr. A. C. Wilson's contention (Jan. 20, p. 96) of the fundamental role of exploitation in various forms in the creation of antisocial unhappiness, and while in complete agreement with him in the first and final paragraphs of his letter, I would like to point out that there is a growing body of psychiatric opinion of a predominantly environmental rather than biological orientation. Such psychiatrists consider that aggressive tendencies are not inherent and inevitable, but are the result of suppressed resentment and hostility in early childhood, and that there must be a "build-up" before there is a breakdown. What is normal and natural in human beings is self-assertion, the "standing up" for the right to live in as happy and reciprocal a conjunction with others as is possible. An important function of psychotherapy is not the discharge of aggression into thin air, so to speak, but the alteration of the force behind it through understanding and insight to a healthy self-assertion and a real self-esteem. Thus, for what Dr. F. E. Williams terms "normal aggression," the concept of adequate self-assertion and true self-evaluation could be more satisfactorily and usefully substituted. Nature indeed is red in tooth and claw, but humanity in the exercise of an evaluating and discriminating consciousness need not necessarily be so.—I am, etc.,

Morpeth. L. F. DONNAN.

Artificial Insemination

SIR,—The writers of the article on artificial insemination have caused an angry eruption on your fair pages, but they have at any rate been instrumental in ventilating a subject on which sooner or later some decision must be reached.

Is insemination with donated semen an ethical proceeding? Many doctors would appear to believe that in all cases and in all circumstances it is inherently immoral. Ethical decisions rest on feeling rather than on argument, and those who believe insemination to be wrong are entitled to their opinion. But to support such an ethical decision with arguments based on the imagined psychological consequences to the parties chiefly involved only weakens the case against insemination. In actual practice the emotional attitude of these parties to the proceeding is quite different from what many of your correspondents would expect it to be. It would be wiser, therefore, for the opponents of insemination to confine their attention to the ethical aspects of this subject.

I have always felt that in the age-long dispute between the vivisectionists and the anti-vivisectionists Mr. Bernard Shaw stood on the firmest ground when he stated simply that knowledge could be purchased at too great a cost, and that the knowledge gained from vivisection was an example of this. Those who have fallen back on the argument that the information to be obtained from animal experiment was misleading and of no value to medicine merely discredited the case against vivisection. So also does such a correspondent as Dr. F. M. R. Walshe obscure the issues when he writes: "It is difficult to argue with the advocates of this latest novelty in techniques offered to the community, for they seem to have no clear ethical principles, and, we may be sure, will be disdainful of those that have." Fortunately we live in a country in which the right is accorded to everybody to have and to express freely their ethical principles. Surely it should be possible for medical men to reach some understanding on this highly controversial subject without discrediting the motives of their fellows? Voltaire once said: "I entirely disagree with your opinion, but I would willingly die in defence of your right to express it."—I am, etc.,

London, W.1. KENNETH WALKER.

SIR,—Prof. L. G. Parsons (Jan. 20, p. 96) appears to be under some misapprehension with regard to the position of a child born as a result of artificial insemination. It is not an illegitimate child as he suggests, and quite clearly the doctor who performs the operation is in no way an accessory to any misdemeanour. Every child born of a married woman during the subsistence of the marriage is presumed to be legitimate, providing the husband and wife have had opportunities of access and neither the husband nor the wife can give evidence tending to disprove the fact of sexual intercourse between them. In those circumstances the child is quite properly registered as legitimate, though it is clear that there is a risk of a third party taking action to bastardize the child, but in that event it would be extremely difficult for that third party to bring the necessary evidence to the court.—I am, etc.,

Llanfairfechan. G. J. FINCH.

SIR,—I would be grateful if you would allow me to reply to the proposals published in the *Journal* on this subject: (1) Women not possessing a husband should be (I presume voluntarily) subjected to artificial insemination. (2) The intelligentsia should act as donors.

These proposals have filled me with horror and amazement. I am surprised that so little consideration has been paid in this controversy to the person most directly concerned—i.e., the offspring. Surely the strength of the nation lies not in its intelligence quotient *per se* but the spirit of its citizens—a spirit bred and fostered by home life and influences. An Englishman's home is his castle, and each home forms a unit which makes up the nation; but the children thus produced would have no home in the present sense of the word, since they would never know, and feel the influence of, their father. Admittedly, there are many children in the country to-day who have unfortunately never known their father if he died during their infancy; nevertheless his influence still pervades the household, since his life is held up to them as a model by their mother for them to emulate, and his memory is both revered and cherished.

Finally, one hears a great deal nowadays about "State control." Surely it is a degradation, and not a social advancement, to suggest that the population shall in future be organized into one vast stud farm?—I am, etc.,

Stoke-on-Trent. AUDREY ROBERTS.

Tapeworm in Freshwater Fish

SIR,—During 1944 two outbreaks of disease in trout, caused by infection with the plerocercoids of a species of *Diphyllobothrium*, were recorded. The first report (Duguid, J. B., and Sheppard, E. M., *J. Path. Bact.*, 1944, **56**, 73) gave details of an epidemic which occurred during 1942–3 in two reservoirs in South Wales, and the second (Hickey, M. D., and Harris, J. R., *British Medical Journal*, 1944, **2**, 310) dealt with the occurrence of the condition in trout in the Dublin area.

The purpose of this letter is to record a third, very mild, outbreak which came to my notice during the latter part of 1944. Diseased trout were first observed during the month of August in a reservoir in Northamptonshire, six dead trout being picked up between August 11 and 25. I was not able to examine any of these, and saw only a seventh trout caught on Sept. 24. Thirty-nine plerocercoids, showing morphological characters similar to those described by Duguid and Sheppard, were recovered from the peritoneal cavity of this trout, and these plerocercoids were fed to one guinea-pig and to three rats. No evidence of infection was observed in the guinea-pig, but all three rats passed eggs of *Diphyllobothrium* in the faeces for varying periods, and finally threw off the infection spontaneously. During the period when deaths were being observed in the trout fifty grebe also died, but it is not known whether or not the dead grebe were infected with *Diphyllobothrium*. Subsequently several lots of smaller fish, including species other than trout and totalling just over 100, were caught in the reservoir, and on examination 40% of them were found to harbour one or more plerocercoids of a smaller type than those recovered from the trout caught on Sept. 24. Attempts to infect rats by feeding these smaller plerocercoids have not, as yet, yielded positive results.—I am, etc.,

T. E. GIBSON.

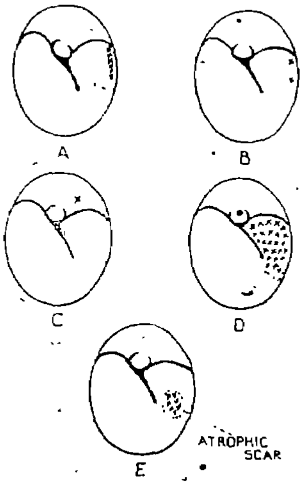
Agriculture and Fisheries, Weybridge.

Eustachian Obstruction and Barotrauma in Airmen

SIR,—The comprehensive article by Fl. Lieut. R. M S. Matthews on Eustachian obstruction and otitic barotrauma in air crews of heavy bombers, published in your issue of Oct. 21, 1944, is of such value that the following criticisms and comments are submitted with diffidence.

He states that to perform Valsalva's manœuvre "it is helpful to incline the head forward with the chin on the chest." Airmen almost invariably *do* incline their heads forward "with the chin on the chest" when asked to auto-inflate; but from observation of several thousand patients (including over 500 cases of acute otitic barotrauma) it has become apparent that the optimum position in which to achieve successful air entry is with the neck extended and the head slightly tilted backwards, so that the tip of the pinna is in the same horizontal plane as the ala of the nose. Although this "feels wrong" to the individuals, they are frequently surprised by their ability to "clear" the ears in this position after auto-inflation has been impossible in flexion. This is not an original observation. In 1866 Lucae pointed out that flexion of the head on the chest rendered ventilation more difficult, and Hartmann (1879) and Perlman (1939) have emphasized the importance of the effect of posture on tubal patency.



Your contributor's remarks on the importance of *visual* recognition of air entry into the middle ear should be stressed, as this is the most frequent and reliable present evidence of air flow into and out of a tympanum with an imperforate drumhead. Very slight outward movements of the drumhead become evident by the appearance of fresh light reflexes additional to the cone of light, and the usual situations of these are shown in the accompanying diagrams of a left tympanic membrane. Usually these light reflexes become visible close to the attached border of the postero-superior quadrant as linear (A) or pin-point (B) areas; less commonly the reflex becomes visible above and behind the short process of the malleus (C). Occasionally, and particularly if the lustre is poor, the whole posterior hemisphere may be seen to bulge outwards (D). This last movement may easily escape detection, and its occurrence may not be obvious until the subject swallows with the anterior nares occluded (Toynbee's manœuvre), when this segment of the tympanic membrane may be seen to move inwards. On scarred drumheads light reflexes may appear elsewhere, or an atrophic patch may be observed to bulge outwards (E).

The 2,000 ears mentioned by Fl. Lieut. Matthews, and in which air entry was visibly positive in 91.7% of cases, belonged to air cadets who had been fully instructed in Valsalva's manœuvre and one-half of whom had varying amounts of flying experience. In a series of *un*instructed ground-crew personnel air entry was visibly positive in only 83%, while in a series of experienced air-crew personnel movement of the tympanic membrane could be seen in 97.5%. These three percentages demonstrate not only the frequency of the positive visual findings but also the value of instruction in Valsalva's manœuvre. The importance of instruction has been emphasized by Fl. Lieut. Matthews, and the study of a considerable series of patients leaves no doubt that, excluding acute upper respiratory infections, ignorance of the correct methods of auto-inflation is the most frequent contributory factor in the causation of acute otitic barotrauma.—I am, etc.,

J. E. G. MCGIBBON.

Medical Reciprocity

SIR,—The letters of Dr. James Burnet (Jan. 6) and of Dr. S. Chaplin (Jan. 20) on the subject of medical reciprocity seem to beg the questions of supply and demand, among others. Dr. Chaplin questions the desirability of "*permitting* [*sic*] such a state between this country and foreigners," in view of the non-acceptance of English (does he mean British?) qualifications in certain parts of the British Empire or in certain Dominions.

It takes at least two to make a bargain, and it may fairly be asked if (to take a specific case) France would be likely to acclaim the project of medical reciprocity with this country, which would, the respective climates being what they are, almost certainly involve the flooding of the French Riviera with qualified refugees (the word is meant literally) from the less equable parts of these mist-wreathed islands. France wisely protected her native practitioners by decreeing that seasonal practices by foreigners (i.e., non-French) were not allowable. This inhibition will certainly be reintroduced, or continued, by the Government of the "Fourth Republic." The foreigner who wishes to practise medicine in France to-day must have a French qualification, and examinations are conducted in the French language. It is, as stated, a matter for the Privy Council at this end. In any case, as the Prime Minister has said in another connexion, there would be no harm in trying—but . . .—I am, etc.,

London, W.1. W. NUNAN.

R.M.B.F. Christmas Gifts

SIR,—It was with the utmost gratification that the late Sir Thomas Barlow received the news that his last "Christmas Gifts Appeal," made when he was in his 100th year, had once again eclipsed all previous records, and had reached the splendid total of £1,817. Had his life been spared Sir Thomas would be personally sending this letter of his most grateful thanks to the medical press, and thereby to the large number of subscribers up and down the country who, by their generosity, have contrived that each year the sum reached has beaten the previous year's record. In particular, the gracious donation of one hundred guineas by the Royal College of Physicians to memorize his entry into his 100th year and to mark the esteem in which his colleagues held him touched Sir Thomas very much and gave him keen pleasure.

On behalf of my committee I tender to one and all our sincerest thanks. We shall continue this annual "Christmas Gifts Appeal" as heretofore. They have been so generously supported and have evoked so much pleasure and gratitude that, although they will lack the inspiration of Sir Thomas Barlow's personality, we feel they have now become an integral part of our work. We are confident that this will be in accordance with the general wish.—I am, etc.,

ARNOLD LAWSON,
Chairman of the Committee of Management.

Royal Medical Benevolent Fund,
London, S.W.15.

Obituary

HAROLD COLLINSON, C.B., C.M.G., D.S.O., M.S., F.R.C.S.

We regret to announce that Mr. Harold Collinson, the eminent Leeds surgeon who held professorships of surgery there for nine years, died on Jan. 25 at Linton, Wetherby, after an illness of two or three months.

Born on Aug. 19, 1876, son of J. W. Collinson of Halifax, he was educated at the great Quaker schools at Ackworth and Bootham, and then studied at the Yorkshire College and the Leeds Medical School. A brilliant academic career culminated in Fellowship of the Royal College of Surgeons within four years of qualification, and the degree of M.S.Lond. in 1907. His first resident post in the General Infirmary at Leeds was that of house-surgeon; later he was for three years resident surgical officer and in 1907 he was elected honorary assistant surgeon, promotion to the full staff coming at the end of the last war. He had held a commission in the R.A.M.C.(T.F.) since 1905 and was mobilized with his unit, the 2nd West Riding Field Ambulance, on Aug. 4, 1914. His distinguished services in France from April, 1915, until the end of the war were recognized by the award of the D.S.O. in 1917, the C.M.G. in 1918, the C.B. in 1919; and he received from the President of the French Republic the honour of Chevalier of the Legion of Honour and the Médaille de la Reconnaissance Française. He rose to the rank of colonel, A.M.S., and was awarded the Territorial Decoration. During the present war he served as group officer, E.M.S., and regional adviser in surgery.

On the academic side at Leeds University Harold Collinson was in turn clinical lecturer in the Faculty of Medicine, professor of clinical surgery (1927–33), professor of surgery (1933–6), and finally dean for five years. Besides his valuable work at the General Infirmary he was also consulting surgeon to St. James's Hospital, Leeds, the Mirfield Memorial Hospital, the Clayton Hospital, the Wakefield and Skipton and District Hospital, and to the West Riding Mental Hospital, Wakefield. He represented the University of Leeds on the General Medical Council from 1936 to 1942. He was a Fellow of the Association of Surgeons of Great Britain and Ireland and a past president of the Leeds and West Riding Medico-Chirurgical Society. He joined the B.M.A. in 1907, was chairman of the Leeds Division in 1935–6, and served on the English and Welsh Consultants and Specialists Group Committee for three years. His published writings were almost wholly on abdominal surgery.

Of the man himself we may quote from an appreciation by "M. J. S." published in the *University of Leeds Medical Magazine* of October, 1941: "Harold Collinson's five-year tenure of the office of dean of the Faculty of Medicine terminated in September last. It was indeed a fortunate coincidence that Prof. Jamieson's departure to Trinity College, Dublin, in 1936 should coincide with Prof. Collinson's retirement from the chair of surgery. Here, immediately available, was the ideal man to be dean, a man infinitely younger than his 60 years, who enjoyed the confidence and respect of all, and who had built up an enviable reputation for straight dealing, integrity, and honesty of purpose. . . . His connexion with our School covers nearly half a century, and his record throughout, as surgeon and teacher, soldier and administrator, has been one of brilliant achievement, unspoilt by any slightest suggestion of self-seeking or hint of the Superior Person. It is not to be wondered at that this kind, generous, and courageous man has made for himself a unique place in the regard and affection of his colleagues and of many generations of students."

JAMES LIVINGSTONE LOUDON, M.D.

We regret to announce the death, in his 80th year, of this well-known Scottish member of the B.M.A. He was educated at the University of Glasgow, of which he was M.D. He was Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow and a D.P.H. Among other medical appointments he had been medical officer of health of the Burgh of Hamilton. Dr. Loudon's interests were widely spread. He was an elder of the kirk, was a Justice of the Peace, a lieut.-colonel, R.A.M.C.(T.F.), with war service in France, and held the T.D. He was a well-read man with a gift for the apt quotation and a strong preference for accuracy in quotation. It was a source of pride to him that he was named after David Livingstone, the explorer, who was a great friend of his father's (also a doctor in Hamilton). Loudon had an interesting collection of mementoes and relics of his namesake. He joined the B.M.A. in 1902, and from then onwards took a very active part in its work. He was for many years secretary and chairman of the Lanarkshire Division and represented it on the Representative Body on several occasions, the last time being at Belfast in 1937. He was a member of the Central Council of the Association in 1912–18, again in 1927–9, and in 1931–6. He was a member of the Scottish Committee from 1927 to 1936, and a past-president of the Glasgow and South-Western Branch.

Dr. Loudon was a welcome figure in B.M.A. circles. Though not a frequent speaker, when he did speak it was obvious that he had something to say. He was conspicuous for his generosity, for his loyalty as a friend, and for the soundness of his judgment, and he will be greatly missed. His eldest daughter is a member of the medical profession and married the M.O.H. for Lanarkshire, Dr. J. M. Lang.

A. T. WILKINSON, M.D., F.R.C.P.

Arthur Thomas Wilkinson, who died at Poynton, Cheshire, on Jan. 21, was born in 1853, received his scientific education in the Owens College, Manchester, and had a much wider general foundation in it than was usual even then. He graduated B.A.Lond. in 1872, and B.Sc. two years later. In his medical education he had an exceptionally brilliant career, being one of those who can acquire knowledge and display it for examination requirements. In the preliminary scientific examination for the London M.B. he was awarded honours in chemistry, zoology, and botany, and in the First M.B. next year won the exhibition and gold medal in organic chemistry, materia medica, and pharmaceutical chemistry, and was third in honours in physiology (1875). He then took in his stride, so to speak, the L.S.A. diploma in 1876 and the M.R.C.S. next year. Having won honours in medicine and obstetrics in his Final M.B. he proceeded M.D. in 1880.

Before qualification Dr. Wilkinson had been physician-assistant at the Manchester Royal Infirmary, one of the last to hold this post, and subsequently was house-physician at the Infirmary and at Ancoats Hospital. General practice followed, and for many years he was one of the anaesthetists at the Royal Infirmary. While acting in this capacity one of his eyes became infected with some septic matter, causing the loss of it and the need for an artificial eye. In 1880 he was appointed assistant medical officer to the hospital, where he worked daily with the honorary staff in the out-patient department and took regular part in the elementary teaching of clinical medicine. With such a fine academical career it might be expected that he would be a good teacher, and though such promise is not always fulfilled it was in his case, and he became a popular and much-sought-after coach for the preliminary and qualifying examinations. His general-practice experience provided many useful hints on how to manage illnesses. One prescription of his had a curiously wide European reputation, for when some Manchester medical workers, including women, were assisting the Russian Army on the fatal Tannenberg front in the last war they found that scabies was treated with what the Russians called Wilkinson's ointment, the formula of which was equal parts of sulphur and ammoniated mercury ointments and of benzoated lard, the last having some special virtue additional to the other two.

He was appointed an honorary assistant physician to the Royal Infirmary in 1892, and remained in active work until his retirement on attaining the age of 60 in 1913. For many years of that time he filled the office of dean of clinical instruction, and his knowledge of the requirements of examining bodies enabled him to give useful advice to students. He lectured in the University on diseases of the kidney, and published some papers on the subject. He took a prominent part in the scientific life of the town, and was president of the medical, pathological, and clinical societies, the last-mentioned one being very popular for many years, until the clinical meetings of the Manchester Medical Society supplied the need for it. Dr. Wilkinson was elected a Fellow of the Royal College of Physicians of London in 1907, having taken the M.R.C.P. in 1888. At the Annual Meeting of the B.M.A. in 1902 he served as secretary of the Section of Medicine. He was a member of the Wesleyan religious body, in which his father had been a well-known minister; and he gave much time and thought to its administration and educational work. For many years he lectured regularly on divinity to students in the College, and was a frequent and welcome occupant of the pulpits of chapels in the district. He had been one of the leading members of a College Social Welfare Society in his student days and earlier years of general practice.

Sir HERBERT SMALLEY, M.D.

Formerly H.M. Commissioner of Prisons

Sir Herbert Smalley died at Hove on Jan. 25. He was the third son of the Rev. Cornwall Smalley, and was born in London on June 3, 1851, and was therefore one of the oldest members of the profession. Educated at St. Paul's School and King's College Hospital he qualified M.R.C.S., L.R.C.P. in 1875, and took the M.D. degree of Durham University in 1891. He was also an Associate of King's College. He joined the Prison Service in March, 1876, and was stationed at Chatham Prison, and served later at Millbank, Dartmoor, Pentonville, Dover, and Parkhurst Prisons. In 1897 he was appointed Medical Inspector of Prisons, and in 1913 was further promoted to the office of H.M. Commissioner of Prisons and a Director of Convict Prisons. His valuable services to the State were recognized when he was knighted in 1913. He retired in 1917. He had been a member of the B.M.A. for 68 years at the time of his death.

It is almost inevitable that a man who reaches his tenth decade will leave at his death no witness to record at first hand his earlier work and ambitions. The fact that Smalley passed the primary examination for the Fellowship of the Royal College of Surgeons and the written testimony of John Curnow, the dean of his medical school, show that he was an able and earnest student. The writer of this note served under Smalley from 1899 until his retirement in 1917, and later, as Commissioner, had special opportunities of estimating the constructive value of Smalley's official work.

It was particularly fortunate that Smalley entered upon his duties as Medical Inspector of Prisons with 20 years' experience behind him as a prison medical officer. In no other way could he have appreciated so fully the peculiar problems which arise in the daily work of a prison medical officer, and no other training could have made him so wise a counsellor in the management of difficult prisoners of either sex. As soon as he became inspector Smalley set to work quietly, unobtrusively, and determinedly to establish the status of the prison medical officers on a firm basis, and, while justly balancing the disciplinary and medical issues arising in the treatment of offenders, advanced the scientific approach to criminal problems. Under his wise guidance the conditions in the prison hospitals were brought into line as far as circumstances permitted with those outside, and he encouraged the medical officers to regard the criminal as a fitting subject for individual study. He prepared the tabulated forms which were used by Goring and other prison medical officers in the anthropometrical survey which Goring analysed in his well-known publication, on *The English Convict.*

As a prison medical officer Smalley had been impressed by the necessity for a special nursing service in prisons, and one of his first cares as inspector was to establish a separate hospital male and female staff. To further his purpose he wrote an excellent *Manual of Prison Hospital Nursing* in 1902. The book was an immediate success and was used far beyond the English Prison Service. Although chiefly interested in general medicine, Smalley was ever mindful of the mental aspects of offenders, and was an authoritative witness before the Royal Commission on the Care and Control of the Feeble-Minded in 1904. His statements in the annual reports of the Prison Commissioners were marked by progressive caution, sound judgment, and a humane and human outlook upon the different problems with which he dealt. His conscientious work, common sense, wise counsel, and sustained determination to conduct the administrative as well as the medical business of the department at a high level of efficiency and humanity were recognized and highly appreciated by his fellow commissioners.

Smalley avoided publicity, but he made the public service his life's work and was content quietly to lay sure foundations upon which those who followed him could build. Those who worked with him, particularly those who succeeded him at the Home Office, know the extent of his very real success. His interest in the prison service continued up to the last. The manner in which he endeared himself to the medical officers was shown by the visits they paid him from time to time in spite of the long passage of years. Indeed, to some of us these visits were a happy pilgrimage. He married in 1885 Rose Christina, daughter of the late G. F. Grammann. There were no children, but perhaps it is not too much to believe that their affection and solicitude one for another contributed to their longevity as well as to their mutual happiness.

W. N. E.

T. HARRISON BUTLER, D.M., F.R.C.S.

Mr. T. Harrison Butler, well known as an ophthalmic surgeon far beyond the Midlands, where he practised for many years, died suddenly at Hampton-in-Arden, Warwickshire, on Jan. 29. He was a past-president of the Ophthalmological Society of the United Kingdom, and gave the Doyne Memorial Lecture (1924), the Montgomery Lectures in Dublin (1926), and the Middlemore Lecture on three occasions.

Thomas Harrison Butler, son of the Rev. G. W. Butler, was born at Stanhope, Co. Durham, on March 18, 1871. From St. Paul's School he entered Corpus Christi College, Oxford, with a scholarship in 1889, and after graduating B.A. with first-class honours in natural science in 1893, went to St. Bartholomew's Hospital. He took his medical degrees at Oxford in 1895, proceeded M.A. and D.M. in 1902, and was elected F.R.C.S. in 1941. He served as house-surgeon at Bart's and house-physician at the Royal Free Hospital, was awarded the Radcliffe Travelling Fellowship of the University of Oxford in 1896, and attended eye clinics at Kiel, Berlin, Dresden, Vienna, and Zurich. For four years he worked as assistant surgeon to the British Ophthalmic Hospital in Jerusalem, and then as plague medical officer at Capetown. On returning to this country he was elected ophthalmic surgeon to the Coventry and Warwickshire Hospital in 1909, to the Warneford Hospital, Leamington, in 1910, and three years later joined the visiting staff of the Birmingham and Midland Eye Hospital: in 1918 he became consulting ophthalmic surgeon to the Hospital of St. Cross, Rugby, and afterwards honorary ophthalmic surgeon to the West Bromwich and District General Hospital. He was a prominent member of the Midland Ophthalmological Society, and active in the work of the Oxford Ophthalmological Congress from the time of its foundation.

The earliest papers by Harrison Butler were on refraction on ophthalmology in Palestine, on tuberculous disease of the uvea, and on the treatment of trichiasis, and he wrote much else on the surgery of the eye, but his name is best known to the profession as an authority on slit-lamp ophthalmoscopy His valuable and most complete *Illustrated Guide to the Slit-Lamp* appeared in 1927; it was a fine piece of work on the use of that instrument in eye disease, to the making of which there had gone much careful observation and accurate recording. The book was founded upon a series of lectures at the University of Oxford, together with the Doyne Memoria Lecture and the Montgomery Lectures. It is believed that the whole of the 158 illustrations in the text and the 21 additiona figures in the five coloured plates were the work of his own skilled hand as a draughtsman.

Harrison Butler joined the B.M.A. in 1897, was vice-president of the Section of Ophthalmology at the Annual Meeting o 1926, and did good work on a number of special subcommittee at headquarters, where his membership of the Ophthalmic Group Committee ran continuously from 1923. Outside hi profession he was an ardent yachtsman, a member of the Royal Cruising Club, and the author of several contributions to yachting journals. As an undergraduate he had rowed in th Corpus VIII, and in later life he became president of the Little Ship Club.

CECIL JOLL, M.Ch., F.R.C.S.

Dr. H. W. Loftus Dale writes from Aylesbury:

Mr. C. A. Joll's untimely death, while a great loss to surger as a whole, is particularly felt by his colleagues at the Royal Buck Hospital, with which he had been associated since 1920. It would be superfluous for me to touch on his brilliance as a surgeon Although it was one of his minor appointments, he had a great affection for the Royal Bucks and did much to raise and maintai its prestige as the county hospital. He always attended person ally and with unfailing punctuality. His own matchless efficienc inspired all those who worked with him to give of their best, with the result that we got through an amazing volume of work which was a constant source of wonder to succeeding generations of residents and theatre sisters; all fell under his spell. I acted as his anaesthetist for 21 years, and his death deprives me of a very great friend and valued colleague; his superb technique made my work for him a real pleasure. He was a mine of information on any subject and possessed a keen sense of humour. His axioms and aphorisms uttered during operations will long be remembered and with profit by all colleagues in Aylesbury, and by many generations of residents. In no circumstance of hazard or of exasperation have I seen him lose his head or his temper; he was only intolerant of inefficiency. He carried on his work here until very shortly before his death, which has deprived us of a surgeon difficult to replace. We have the memory of a loyal friend and colleague which time will not readily efface.

We regret to announce the death on Jan. 12 at his home in Dublin of Dr. **JOHN AGAR MATSON**, a former President of the Royal College of Physicians of Ireland and consulting physician to the Richmond and other Dublin hospitals. Dr. Matson studied at Trinity College, Dublin, graduated B.A. in 1886, M.B., B.Ch., B.A.O. in 1888, and M.D. in 1889; he also obtained a special certificate in gynaecology when taking the licence in midwifery at the Rotunda Hospital. After qualification he spent some time in England as clinical assistant to the Great Northern Central Hospital, London, and house-surgeon to the Royal Southern Hospital, Liverpool. On returning to Dublin he worked as resident at the Mater Misericordiae Hospital. Dr. Matson took the licence of the Royal College of Physicians of Ireland in 1901, the Membership in 1903, and was elected a Fellow in 1904. He served as censor in medicine, held office as Vice-President of the College in 1929, and was President in 1934; he also acted as censor in medicine for the Irish Royal College of Surgeons. He published clinical papers in the *Transactions of the Royal Academy of Medicine in Ireland* and in the *Dublin Journal of Medical Sciences.* Dr. Matson joined the British Medical Association as long ago as 1889.

We regret to record the death on Jan. 24 of **DAVID LIVINGSTON HAMILTON** at Cambridge. He was born on Jan. 27, 1864, and was educated at Ledwich and Carmichael College, Dublin, and Owens College, Manchester, qualifying L.R.C.P. and L.R.C.S.Ed. and L.R.F.P.S.Glas. in 1887 and L.M. Coombe Hospital in 1886. He obtained the F.R.C.S.Ed. in 1895. In 1902 he was elected honorary anaesthetist to the Southern Hospital, Manchester. Dr. Hamilton practised for many years at Great Missenden, Bucks, and later at Dover. On being evacuated from Dover in 1941 he purchased a practice at Cambridge and continued to work there until a few days before his death. He was a much-loved doctor, and his unfailing kindness caused his patients to look up to him not only as their physician but as their guide and friend. Though his practice was extensive he never failed to keep himself abreast of new advances. For many years he was a keen Volunteer and Territorial officer, and was promoted lieut.-col. in the R.A.M.C.(T.) in 1911. During the 1914–18 war he commanded No. 82 Field Ambulance in France and was later appointed D.A.D.M.S. to the 1st Army in England. He took a considerable interest in the St. John Ambulance Brigade and was awarded the honour of Serving Brother in 1934. He married in 1885 Miss Helen Ida Bagge, who died in 1903, and in 1922 he married Miss Gertrude Marshall, whose devoted care did much to enable him to carry on a busy practice to the advanced age of 80. His family consisted of three sons, all of whom are now serving in the Forces, and two daughters.

The Services

Lieut.-Gen. Sir James A. Hartigan, K.C.B., C.M.G., D.S.O., has been appointed Colonel Commandant of the R.A.M.C. for 1945, and Major-Gen. J. P. Helliwell, C.B.E., M.R.C.S., Colonel Commandant of the Army Dental Corps for 1945.

The name of Fl. Lieut. R. V. Robinson, R.A.F.V.R., was omitted from the list of Air Force medical officers mentioned in dispatches (*Journal*, Jan. 20, p. 98).

CASUALTIES IN THE MEDICAL SERVICES

Died from injuries.—Lieut.-Col. Martin Patrick Conroy, I.M.S.

Prisoner of war.—Capt. J. W. Logan, D.S.O., R.A.M.C.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a Congregation held on Jan. 26 the following medical degrees were conferred:

M.B., B.CHIR.—*J. D. Andrew, E. L. Arnold, D. V. Bates, *T. C. Beard, W. M. Bennett, J. H. E. Bergin, I. J. Carré, W. R. Cole, *C. H. de Boer, E. D. Dyson, T. P. S. Frew, S. A. M. Garibian, H. McC. Giles, P. F. Haggart, F. G. J. Hayhoe, P. R. Headley, J. G. Holmes, D. G. James, E. G. Jenner, E. D. Jones, J. D. S. Knight, A. G. Leatham, P. F. Lucas, E. T. G. Meade-Waldo, J. M. Morgan, M. W. L. Mutch, E. W. Nation, W. J. Naunton, G. A. Newsholme, D. A. Pond, P. K. Robinson, G. H. Searle, K W. Symons, *J. M. Thomas, W. E. W. Tilleke, *J. Upsdell, D. P. Wheatley, R. A. Womersley, K. A. A. Wray, M. F. T. Yealland.

B.CHIR.—R. O. Lee.

* In person.

ROYAL COLLEGE OF OBSTETRICIANS AND GYNAECOLOGISTS

At a meeting of Council held on Jan. 27, with the President, Mr Eardley Holland, in the chair, the following candidates were elected to the Membership:

Amelia E. Burch, J. P. O. Erskine, E. Garland-Collins, A. B. Hay, J. Karnicki, Gladys E. Keith, Dorothea M. Kerslake, Sybil G. Mocatta, Dorothy M. Shotton, B. G. G. Spiers, Dorothy J. Thompson.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

At a quarterly comitia of the Royal College of Physicians of London held on Jan. 25, with the President, Lord Moran, in the chair, it was announced that a committee was being set up to consider the problems arising out of demobilization. A memorandum was received on the future organization of the psychiatric services.

The following candidates, having satisfied the Censors' Board, were elected Members of the College:

J. F. Ackroyd, M.B.Brist.; *G. M. Barrett, M.B.Camb., Lieut., R.A.M.C.; *M. P. Bhagat, M.D.Bombay; Georgiana M. Bonser, M.D.Manch.; R. J Cairns, M.B.Lond.; *P. L. C. Carrier, M.D.Lond., Lieut.-Col., R.A.M.C.; *L. B. Carruthers, M.D.Kingston, Ontario; *P. K. Chattopadhyay, M.B.Calcutta; *N. S. Clark, M.B.Aberd., Major, R.A.M.C.; *A. M. Dawes, M.B.Lond., Capt., R.A.M.C.; D. P. Degenhardt, M.B.Ed.; C. E. Dent, M.B.Lond.; M. A. Floyer, M.B.Camb.; *R. H. Girdwood, M.B.Ed., Capt., R.A.M.C.; T. A. Grimson, M.B.Lond.; R. H. R. Hartley, L.R.C.P.; C. F Hawkins, M.B.Lond.; T. C. Highton, M.B.Liverp., Temp. Surg. Lieut., R.N.V.R.; *J. C. Houston, M.B.Lond., Capt., R.A.M.C.; E. A. Hunter, M.B.Lond.; M. R. Jeffrey, M.B.Camb.; A. T. Jones, M.D.Liverp.; *M. R. Joseph, Major, R.A.M.C.; *A. C. Kendall, M.B.Birm., Capt., R.A.M.C.; *H. S. Khandheria, M.B.Bombay; H. Levy, M.D.Berne; G. M. Little, M.B.Camb.; S. Locket, L.R.C.P.; *D. Macaulay, M.B.Glas., Capt., I.A.M.C.; *J. G. McGill, M.D.Belf., Capt., R.A.M.C.; W. A. Maclure, M.B.Glas., Surg. Lieut., R.N.V.R.; W. Mayer-Gross, M.D.Heidelberg; *J. K. Mehta, M.D.Bombay; *A. B. Mukerjee, M.B.Calcutta; J. M. Naish, M.B.Camb., Surg. Lieut., R.N.V.R.; *M. J. Parsonage, M.B.Manch., Capt., R.A.M.C.; *S. Renfrew, M.B.Glas., Capt., R.A.M.C.; *J. L. Reynolds, M.B.New Zeal., Capt., R.A.M.C.; *E. N. Rowlands, M.D.Manch., Major, R.A.M.C.; R. D. W. Schofield, M.B.Lond.; *S. M. Shah, M.B.Bombay; E. G. Sita, M.B.Camb., Surg. Lieut., R.N.V.R.; J. Sondheimer, M.B.Lond.; *R. Subramaniam, M.D.Madras; G. I. M. Swyer, B.M.Oxon.; Margaret D. Thompson, M.B.Birm.; R. D. Tonkin, M.B.Lond., Fl. Lieut., R.A.F.; *W. D. Wallace, M.B.Sheffield, Capt., R.A.M.C.; *M. Ware, M.B.Lond., Capt., R.A.M.C.; B. G. Wells, M.B.Lond.; J. R. F. Williams, M.B.Lond.; *A. W. Woodruff, M.D.Durham, Squad. Ldr., R.A.F.

* *In absentia.*

Licences to practise were granted to the following 125 candidates (including 19 women) who had passed the Final Examinations in Medicine, Surgery, and Midwifery of the Conjoint Board, and have complied with the necessary by-laws:

Hildegard C. Abraham, R. A. Allen, Alison H. C. Alwyn-Smith, R. Andrew, E. A. Balls, W. A. D. Barwise, M. A. Bernays, A. E. Bernstien, K. A. Bhagan, F. J. A. H. Blackwood, R. A. Boland, Daphne V. Bousfield, R. G. L. Brittain, B. H. Brock, A. S. V. Burgen, J. S. Campbell, R. J. F. Campbell, A. A. Cohen, D. H. P. Cope, H. J. P. Davies, Margaret E. Davies, R. De Vere, D. Dooley, E. J. Dowling, J. M. Drew, M. W. Eddings, K. A. Elliott, T. Ellis, Edith M. Evans, T. A. Evershed, R. C. Farrow, Ruth M. Fawcett, N. R. Fenton, W. N. Fitzpatrick, M. W. Fordham, W. P. Foster, A. T. H. Glanvill, F. J. Goodey, M. V. Guilmant, K. J. Gurling, J. Harding Cox, Mary L. Hare, J. E. Holgate, J. G. Holmes, E. H. Hopkinson, Dorothy I. Howes, Mary P. Hughes, M. F. Hunt, Flavia Z. L. B. James, R. M. Jenner, Moyra P. C. Johnsen, E. D. Jones, S. Jones, I. M. Kahan, A. P. Kalra, W. de M. Kellock, D. R. Laurence, S. Levine, D. O. Lloyd, H. R. Lomax, Margaret D. T. Lord, G. E. Luke, R. P. C. MacDonald, Kathleen M. M. McDougall, J. R. Macintyre, C. B. McKerrow, D. MacKinnon, Nora S. McRaith, H. B. Marsden, J. D. Martin, S. Mason, G. Mizbah, M. G Moore, A. V. Morse, E. W. Nation, G. F. Newbold, D. R. L. Newton, D. P. Nicholson, T. M. Nott-Bower, P. R. Ormrod, G. P. Oxborrow, G. Pollitt, Jean P. Popple, R. W. Povey, T. H. Powell, I. H. Pratt, J. M. Reed, A. P. Roberts, J. M. Roberts, J. H. Robinson, G. J. Romanes, G. A. Rundle, E. L. N. S. Sack, R. G. H. Salkeld, A. O. Sankey, H. Schwartz, M. G. Scott, Elizabeth M. Sefton, J. Sharp, A. F. Sheldon, D. W. S. Sheldon, C. B. Sherer, J. P. Shillingford, S. Shubsachs, D. B. Spanton, J. Stafford, G. W. Storey, H. D. Symon, S. D. Tejani, A. E. Thomas, Betty Thomas, J. L. Thomas, N. A. Thorne, C. Todd, G. Twynholm-Mason, Vivian M. N. Usborne, P. H. Vernon, P. Watson, P. Weinstein, D. P. Wheatley, P. J. Wilkinson, Olwen D. Williams, D. H. Woodhead, M. F. T. Yealland, G. Yerbury.

Diplomas in Child Health and in Anaesthetics were granted jointly with the Royal College of Surgeons of England to the candidates whose names were published in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of Dec. 30, 1944 (p. 871) and Diplomas in Public Health, in Psychological

Medicine, and in Laryngology and Otology were granted jointly with the Royal College of Surgeons of England to the candidates whose names were published in the report of the meeting of the Royal College of Surgeons of England in the *Journal* of Jan. 27 (p. 135).

CONJOINT BOARD IN SCOTLAND

The following candidates, having passed the requisite examinations, have been admitted L.R.C.P.Ed., L.R.C.S.Ed., L.R.F.P.&S.Glas.:

W. C. Adam, J. H. Beckford, M. G. Blackwood, G. W. Blueglass, W. J. Connelly, A. W. Craig, B. Cutler, A. A. Donaldson, L. P. Eaton, J. Fegan, T. M. Glaister, S. M. Harris, Cacilla M. Hofer, Jean Hughes, J. D. Jack, S. Jesner, Helen T. Kilpatrick, S. J. MacKinnon, A. McKirdy, W. D. MacLennan, A. B. Marshall, A. L. Nowell, D. Peebles, D. R. L. Peill, F. C. Place, W. Roberts, J. Rubin, D. G. Scott, A. A. El Serougi, B. M. Steen.

SOCIETY OF APOTHECARIES OF LONDON

Mr. Eardley Holland, President of the Royal College of Obstetricians and Gynaecologists, will deliver a lecture on "The New Obstetrics and Gynaecology" at Apothecaries' Hall, Black Friars Lane, Queen Victoria Street, E.C., on Tuesday, Feb. 20, at 2.30 p.m. Members of the medical profession and senior students are invited to attend.

Medical Notes in Parliament

Relief for Channel Islands

In the House of Lords on Jan. 30 the EARL OF MUNSTER, replying to Lord Portsea, said that the Government was doing everything it could to supplement the basic rations of the civil population in the Channel Islands. Representatives of the International Red Cross, who had visited the islands, stated that the unloading and disposal of the supplies taken in her first voyage by the *Vega* had proceeded satisfactorily, and he took it that the supplies were now in the hands of the civil population. The *Vega* was damaged in harbour in Guernsey, and repairs had become necessary, but she would sail on her second trip on Feb. 1. When she sailed again she would carry as many as possible of the articles which were recommended by the Red Cross representative. The stores she would carry would include soap and salt, medical supplies and drugs, and more food parcels, and would do a great deal to alleviate the position. The question of evacuating seriously ill persons who could not receive proper medical attention in the islands was discussed by the Red Cross representatives, and the matter was being actively pursued by the Government.

Medical Care of Returned P.O.W.

On Jan. 30 Sir ERNEST GRAHAM-LITTLE asked the Minister of Health whether he would inquire into the medical accommodation supplied to prisoners of war on their return to this country with a view to its improvement; and if he was aware that the conditions provided for prisoners with tuberculosis were such as to disturb Service welfare workers. Mr. WILLINK: Returning prisoners of war have the benefit of all the resources of the Emergency Hospital Scheme, where the Service Department concerned requests that they be treated under that scheme. As regards those suffering from tuberculosis whose condition calls for sanatorium treatment, special measures are taken to secure their admission to a sanatorium, but in the present difficulties of limited accommodation it is not always possible to avoid a short waiting period at home, during which the patient is under the expert care of the tuberculosis officer. If Sir Ernest Graham-Little has in mind any particular case for which he considers that inadequate provision has been made I shall be glad to make inquiries.

Women Doctors in Government Departments

On Jan. 23 Capt. PRESCOTT asked the Chancellor of the Exchequer whether there was a general ban on the employment in Government Departments of married women doctors; and whether, in view of their special qualifications, especially for employment in the Ministry of Health, he would consider action to secure their employment in suitable cases. Sir JOHN ANDERSON: The normal rule is that married women are ineligible for appointment to established posts in the Civil Service, and that women holding such posts should be required to resign on marriage; but an exception may be made, upon application by the woman concerned, in any case where it is considered that the employment of a married woman is advisable in the light of her special qualifications, or special experience in relation to the duties required of her, or of the special requirements of the Department concerned. In view of the power to make exceptions in such cases, no special action seems to be needed in relation to women doctors.

Capt. PRESCOTT: In view of the shortage of doctors at the present time—a shortage which is likely to continue in the future—and of the special adaptability of women doctors for certain branches of the Service, ought not the general ban to be lifted? Sir JOHN ANDERSON: The case of doctors is certainly very special, and, as I have just explained, the general rule can be relaxed. I know of no case in which permission has been refused to a woman doctor. Capt. PRESCOTT asked why the ban should be retained, and if it was not redundant but Sir JOHN ANDERSON replied that that was a matter of debate

Nurses Bill

In the House of Lords on Jan. 23 the EARL OF LISTOWEL moved the second reading of the Nurses Bill, the object of which is to correct a drafting error in the Nurses Act and the Nurses (Scotland) Act. He explained that these Acts were intended to protect private patients or hospital authorities from unfair treatment—such as demands for excessive fees or the ministrations of unqualified nurses—on the part of nursing agencies to which they applied for assistance in cases of illness Certain conditions to which these agencies, or nurses' co-operations, had to conform were laid down in the two Acts, in order to prevent these abuses, but the expression "agency for the supply of nurses" was so drafted that it might be taken to cover innocuous organizations like county and district nursing associations. The only way to safeguard these associations and the district nurses, as well as to apply the necessary control to the nurses' co-operations, was to narrow down the meaning of "agency for the supply of nurses" and exclude from the regulations those excellent bodies with which no one had eve desired to interfere. This the Bill did. The Bill was read a second time.

Sale of T.T. Cattle.—Mr. TOM WILLIAMS on Jan. 25 told Gen Clifton Brown that cows which had passed a tuberculin test were being sold at markets as such, though they had not come from tuberculin-tested herds. The only markets subject to official regulation as to the classes of cattle that might be sold were thos authorized under the Tuberculosis (Attested Herds) Scheme. At such markets the only cattle that could now be sold were cattle from herds within this scheme, and cattle from herds licensed for th production of tuberculin-tested milk.

Notes in Brief

In 1943, 5,796 people were killed on the roads and 116,740 wer injured. In the first 11 months of 1944 the corresponding figure were 5,807 and 112,833.

A scheme is under consideration for the control of malaria in Mauritius involving capital expenditure estimated to amount to £1,500,000. Antimalarial work is being carried out in the island.

Medical News

Sir John Boyd Orr, M.D., F.R.S., has resigned the post o director of the Rowett Research Institute, Bucksburn, Aberdeenshire and the vacancy will be advertised at an early date. The pos carries with it the directorship of the Imperial Bureau of Nutrition and the editorship of *Nutrition Abstracts and Reviews.*

At the next meeting of the Royal Society of Tropical Medicine and Hygiene, to be held at 26, Portland Place, W., on Thursday Feb. 15, at 3 p.m., Prof. P. A. Buxton, F.R.S., will read a paper on the use of the new insecticide D.D.T. in relation to the problem of tropical medicine.

A meeting of the Middlesex County Medical Society will be hel at Staines County Hospital on Thursday, Feb. 22, at 3 p.m., whe papers will be read by Dr. A. Barham-Carter on "The Treatmen of Some Hysterical Manifestations," and Mr. N. M. Matheson o "The Diagnosis of Urinary Tuberculosis." A discussion wi follow.

The Chadwick Trust has arranged the following lectures: Tuesday Feb. 20, 2.30 p.m., at Royal Society of Tropical Medicine an Hygiene, 26, Portland Place, W., Dr. J. D. Rolleston, "The Wa and Infectious Disease." Tuesday, March 13, 2.30 p.m., at Londo School of Hygiene and Tropical Medicine, Keppel Street, W.C Dr. Albert Parker, "Atmospheric Pollution." Tuesday, April 1 2.30 p.m., at Royal Sanitary Institute, 90, Buckingham Palace Road S.W., Mr. A. Trystan Edwards, "Sunlight and Sanitation in Relation to the Planning of Buildings." Tuesday, May 8, 2.30 p.m., a Royal Society of Tropical Medicine and Hygiene, Mr. Eardle Holland, "On the Importance of a Maternity Service in the Life o the Nation." Thursday, June 14, 4 p.m., at Chelsea Physic Garden Swan Walk, S.W., Mr. C. J. Layton, "Health and Horticulture. Admission to all the lectures is free and tickets are not required.

Dr. Simon Wigoder has been elected alderman and returnin officer for the North Ward of the Borough of Morley.

The Royal Sanitary Institute announces the following sessional meetings: Feb. 24, at 10.30 a.m., at Radiant House, Bold Street, Liverpool; papers on "Public Health and the Social Services," by Dr. C. O. Stallybrass, and "Post-war Housing," by Mr. L. H. Keay. March 10, at 10.30 a.m., at Westover Senior School, Wembdon Road, Bridgwater; papers on "Water Supply Problems in Rural Districts," by Sir William Savage and Mr. A. J. Allen. March 14, at 2.30 p.m., at Royal Sanitary Institute, 90, Buckingham Palace Road, S.W.; paper on "Insect Pests in Food," by Mr. V. Wadsworth. March 17, at 10.30 a.m., at Norwich Guildhall; papers on "Rat Destruction Work in Norwich," by Mr. G. D. Kirby, and "Food Poisoning," by Dr. A. J. Macdonald. The Cheshunt sessional meeting arranged for March 2, announced in the *Journal* of Jan. 13 (p. 65), has been cancelled.

Dr. Norman Macfadyen, chairman of the Executive Committee of the Town and Country Planning Association from 1929 to 1944, was recently presented at the headquarters in London with the Howard Memorial Medal.

The Sir Robert Jones Gold Medal for 1944 has been awarded by the British Orthopaedic Association to Mr. F. G. St. Clair Strange, F.R.C.S., for his essay on "The Major Amputation Stump in Health and Disease," read at a recent meeting of the association.

The Minister of Fuel and Power has appointed Prof. J. M. Mackintosh, M.D., a member of the Fuel and Power Advisory Council.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* infectious diseases increased in prevalence, the rises over last week's totals being: measles 1,075, scarlet fever 234, whooping-cough 107, dysentery 75, diphtheria 59, cerebrospinal fever 24.

The rise in diphtheria was due to a serious local outbreak in Caernarvonshire, Bangor M.B., where 55 cases, a little more than one-tenth of the total of the whole country, were reported. There was a small increase in scarlet fever notifications in most areas; Lancashire reported 77 more cases than last week, and Yorks West Riding 32. The rise in whooping-cough was greatest in Wales, where notifications exceeded last week's total by 43. Increases in measles were as follows: Yorks West Riding 254, Derbyshire 147, Nottinghamshire 145, Staffordshire 129, Middlesex 109, Essex 98, Lancashire 94, London 80. In Warwickshire notifications dropped by 146, and in Durham by 52. Eight of the 11 cases of typhoid were reported from Lancashire (Manchester C.B. 6, Liverpool C.B. 1, Warrington R.D. 1). The total for cerebrospinal fever was the largest for nine months; the cases were widely spread throughout the country, involving twenty-eight counties, although half the cases were reported from four counties: Lancashire 14, Yorks West Riding 10, Warwickshire 8, Durham 7.

Ninety-two cases of dysentery were notified in Yorks West Riding—8 fewer than last week; the chief centres of infection were Wakefield C.B. 64, and Sheffield C.B. 18. In Buckinghamshire, Aylesbury R.D., the notifications rose from 14 to 62. The other large returns were London 45, Gloucestershire 20, Essex 19, Lancashire 18, Middlesex 10, Suffolk 10.

Almost 100 civilians who have been in contact with the smallpox case at an Army camp in Anglesey have been traced. These are being kept under observation in the absence of isolation facilities. Only a few persons have taken advantage of the free vaccination offer.

In *Scotland* scarlet fever notifications were 33 higher than last week, and those for acute primary pneumonia 25; there were 313 fewer cases of measles, 95 fewer of whooping-cough, and 21 fewer of diphtheria. Although dysentery notifications fell by 7 cases for the whole country, the western area showed an increase of 10, the chief returns being Glasgow 22, Falkirk 11, and Clackmannan County 9.

In *Eire* diphtheria notifications dropped by 16 cases to a total of 97, the lowest for recent months. Delayed returns in Waterford C.B. accounted for the apparently large rise in the incidence of dysentery.

In *Northern Ireland* measles notifications were at the lowest level since the beginning of November, 57 fewer cases being reported than last week.

Week Ending January 27

The returns of infectious diseases in England and Wales during the week included: scarlet fever 1,510, whooping-cough 1,625, diphtheria 450, measles 12,941, acute pneumonia 1,397, cerebrospinal fever 81, dysentery 295, paratyphoid 3, typhoid 3. Eighty-seven deaths were attributed to influenza in the great towns.

No. 3

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 20.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.
